Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods, they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence, or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

This book is written for the general pathologist, the dermatopathologist, the dermatologist with an interest in pathology, residents in training, and other medical and dental specialists interested in understanding the clinicopathologic correlations of oral disease. For clinicians using this book, two appendixes provide information on how to manage mucosal disease.

The objective is to present specific histologic criteria for the diagnosis of inflammatory conditions, cysts, and tumors seen in the oral cavity; illustrate the spectrum of histologic findings, correlating them with the clinical manifestations; and provide histologic differential diagnoses for these entities. This is particularly important in understanding inflammatory mucosal diseases that are relapsing or remitting, in which the histologic findings depend greatly on the stage of the disease, the site of the biopsy, and whether lesions have been treated. The chapter on diagnosis of oral dysplasia discusses not only the conventional cytologic criteria of dysplasia but also the architectural features that are often overlooked.

I have the great advantage of working with clinicians who in this digital age often send their biopsy specimens accompanied by photographs and radiographs of the lesions. I also see many patients in my clinical practice on whom I have performed biopsies. Correlating the clinical appearance of lesions with the histopathology facilitates a better understanding of how mucosal diseases evolve and how subtle and varied histopathologic findings may be.

As with any other textbook or atlas, page limitations required that I be selective in choosing the conditions and appropriate references to be included. Many references are now readily identified and downloaded via the Internet. Nevertheless, I hope that you will find this atlas informative and useful in your practice of pathology.

Acknowledgments

I am indebted to my colleagues and friends who contributed slides and images for this atlas, and to the many clinicians who contribute cases to our biopsy service, thereby supporting the graduate oral and maxillofacial pathology training program at the Harvard School of Dental Medicine. Some of the cases came to me through my participation in continuing competency programs provided by the Armed Forces Institute of Pathology and the American Board of Oral and Maxillofacial Pathology, and from continuing education seminars that I attended at our annual academy meetings. Grateful thanks are due also to my colleagues at the Ohio State University, Columbus, Ohio; Oral Pathology Laboratories, Queens, New York; and colleagues in Guatemala with whom I exchange study sets. This endeavor would have been less than what it is without the patients who generously shared their stories and insights about their diseases and whose images appear within these pages; it is an honor to care for them. All the photomicrographs were taken by the incomparable Dr. Phillip McKee.

1 INTRODUCTION

CHAPTER CONTENTS

Pathology of the oral cavity affects the following structures: (1) the mucosa, (2) the salivary glands, and (3) the jaw bones. Lesions may extend into the oropharynx, sinuses, and the skin. As such, the scope of practice of oral and maxillofacial pathology overlaps with head and neck pathology, dermatopathology, and orthopedic pathology. The oral cavity is also the primary site for the development of lymphomas and many soft tissue tumors, and is also sometimes the location of metastatic tumors. This atlas focuses on pathology that is frequently seen in the oral cavity.

Unlike the skin, mucosal lesions in the oral cavity may manifest only in a limited number of ways—erythematous, white (from keratosis or underlying fibrosis), yellow (from fibrinous exudate), papillary, diffuse or nodular swelling, mass, erosive or vesicobullous, and pigmented. It is important for the pathologist to be familiar with clinical presentations of mucosal disease because this affects the final diagnosis and is particularly important for keratotic lesions, leukoplakias, and mucosal disease.

ANATOMY

The oral mucosa varies clinically and histologically from site to site, and can be divided into keratinized and nonkeratinized mucosa (Fig. 1-1). Knowledge of clinical aspects of oral disease must be correlated with oral anatomy: for example, recurrent aphthous ulcers occur primarily on the nonkeratinized mucosa, whereas recurrent herpes simplex infections occur almost exclusively on the keratinized mucosa in immune-competent patients. The tongue dorsum but not ventrum is specialized for gustatory, masticatory, and deglutition functions. Taste buds are present within fungiform (dorsum), circumvallate (8 to 14 on the posterior dorsum), and foliate (posterior lateral tongue) papillae but not within filiform papillae (Fig. 1-2). The oral mucosa contains no submucosa per se because there is no muscularis mucosa or any other clearly recognizable histologic landmark that separates mucosa from submucosa. As such, the terms *papillary, superficial*, and *deep lamina propria* are preferable to *submucosa*. In general, the epithelium of the oral cavity is much thicker than that of the skin (Table 1-1; Figs. 1-3 to 1-9). Muscle is present fairly superficially on the tongue and slightly deeper on the buccal and labial mucosa. Minor salivary glands are predominantly mucous, although serous acini and demilunes are frequently seen (Fig. 1-10); they are present everywhere in the mouth except on the attached gingiva and tongue dorsum. Serous salivary glands with a smaller mucous component are frequently encountered on the anterior ventral (glands of Blandin-Nuhn) and posterior lateral and dorsal (glands of von Ebner) tongue, often invested in muscle. Lingual tonsils are located on the posterior dorsum and posterior lateral tongue.

TEETH

Teeth are made up mostly of tubular dentin that is capped by a thin shell of very hard but brittle enamel in the tooth crown. The tooth root is surrounded by a thin layer of cementum. The periodontal membrane (made up mainly of type I collagen) attaches to the cementum on one side and the alveolar bone on the other, allowing for slight movement of teeth within the bone (Fig. 1-11).

Enamel (ectodermal in nature) is 96% mineral (hydroxyapatite crystals) and 4% organic material and water. The organic material consists of noncollagenous proteins called amelogenins (90%), enamelin, and ameloblastin. Mature tubular dentin is composed of 70% inorganic material, 20% organic material, and 10% water. The organic base is composed of 90% collagen (mainly type I), dentin matrix, and bone matrix proteins such as osteocalcin, osteopontin, and bone sialoprotein. Dentin is deposited by the odontoblast (of neural crest derivation) and wraps around an odontoblastic process that traverses the entire thickness of the dentin from the pulp where the odontoblast resides, to the enamel or cementum. Cementum is closest to bone in composition with 45% to 50% hydroxyapatite and 50% collagen and noncollagenous matrix proteins. Type I collagen constitutes 90% of the nonmineral portion of cementum.

TABLE 1-1 Histology of Oral Mucosa at Different Sites

Site	Appearance
Nonkeratinized (thick) Buccal mucosa Labial mucosa	Buccal and labial mucosa are contiguous and similar (see Fig. 1-3) 15–20 layers of keratinocytes Broad, tapered rete ridges Loose fibrovascular tissue in the lamina propria or corium; muscle at the base
Nonkeratinized (intermediate) Nonattached gingiva	Nonattached gingiva Intermediate between buccal mucosa and floor of mouth
Nonkeratinized (thin) Floor of mouth Ventral tongue Soft palate/fauces	Floor of mouth and ventral tongue are contiguous and similar to soft palate (see Fig. 1-4) 10–15 layers of keratinocytes Short or poorly formed rete ridges Ventral tongue in the anterior and posterior often contains serous salivary glands (glands of Blandin-Nuhn and von Ebner, respectively) (see Fig. 1-5)
Keratinized Hard palatal mucosa Attached gingiva	Hard palatal mucosa and attached gingiva are similar (see Fig. 1-6) Thin layer of orthokeratin with thin granular layer 15–20 layers of keratinocytes Gingiva has more tapered, slender rete ridges Dense fibrous tissue and periosteum at the base Hard palatal mucosa often has fatty tissue investing neurovascular bundles and minor salivary glands Gingiva may contain rests of odontogenic epithelium (rests of Serres) (see Fig. 1-7)
Keratinized and specialized Tongue dorsum	Moderate-to-thick layer of parakeratin Filiform papillae are keratin spires surrounded by bacterial colonies (see Fig. 1-8) 20–30 layers of keratinocytes Fungiform, circumvallate, and foliate papillae are fibrovascular polypoid structures containing taste buds (see Fig. 1-9) Posterior dorsum and lateral tongue contain lingual tonsils. Skeletal muscle is superficial

Tooth Numbering System and Nomenclature

There are three commonly used nomenclatures for tooth identification. In the American Dental Association (ADA) system each tooth is identified by one number (#1 to #32 starting from the right maxillary third molar moving clockwise) (Fig. 1-12). Palmer's notation (used mainly by the British) and the system adopted by the Federation Dentaire Internationale (FDI) use a single number for each of the eight teeth in a quadrant (starting from the central incisor [#1] moving posteriorly to the third molar [#8]). In the FDI system, a qualifier is added for the specific quadrant in which the tooth is located (quadrants 1 to 4 clockwise starting from the right maxilla); quadrant 1 is right maxilla, 2 is left maxilla, 3 is left mandible, and 4 is right mandible. For example, tooth #12 by the ADA system is the left maxillary first premolar or bicuspid. By Palmer's notation, this is designated left upper 4 or $\lfloor\underline{4}$, and by the FDI system it is tooth 24 (quadrant 2, tooth #4).

The terms *facial, buccal*, and *labial* refer to the aspect of the gingiva or teeth that are in contact with the labial or buccal mucosa and oriented outwards. Conversely, the terms *palatal* and *lingual* are used for aspects that are oriented inwards toward the palate or the tongue.

DIAGNOSIS AND MANAGEMENT

Small macules, papules, or nodules should be excised with a shave biopsy or an elliptical wedge excision. For larger lesions, biopsies using a 3 to 5 mm skin punch provide tissue that is easy to orient for processing; primary closure with one to two sutures is readily achieved (Fig. 1-13). However, the mucosa of the hard palate and gingiva abut directly on the periosteum, and it is difficult to obtain primary closure. The use of silver nitrate or aluminum chloride to control hemostasis is preferable. For the purposes of the clinician, Appendixes A and B at the end of the book provide the most commonly used medications for definitive treatment of mucosal disease and agents for topical pain control.

SOME BASIC GUIDELINES

The histopathologic features of inflammatory mucosal disorders depend on the stage at which the lesion is biopsied (evolving or resolving) and whether it has been treated. The "typical" or "classic" histology for many inflammatory conditions are seen in untreated fully-evolved lesions. As such, a range of histopathologic features is presented for common inflammatory lesions.

Dysplastic conditions are probably the most challenging, because the clinical appearance of the lesion plays an important role in the accurate diagnosis of dysplasia. To this end, clinicians are encouraged to send a photograph of the lesion with the biopsy. Many dysplastic oral lesions show architectural rather than cytologic evidence of dysplasia. These concepts are covered in depth in Chapter 11.

The teeth and salivary glands are adnexa of the oral cavity in the same way that hair and sweat glands are

skin adnexa. As such, there are histologic similarities between odontogenic, salivary gland, skin adnexal, and breast neoplasms. The diagnosis of odontogenic cysts and tumors and many bone-forming lesions can be accurately rendered only if radiographic images are provided and this is particularly true for fibroosseous lesions.

2 Developmental and Congenital Conditions

CHAPTER CONTENTS

Diffuse White Lesions

Diffuse white developmental conditions are often dyskeratotic lesions and represent oral manifestations of genodermatoses. Oral lesions seen in dyskeratosis congenita are usually oral dysplasias/leukoplakias; oral lesions of pachyonychia congenita are rarely biopsied. Oral lesions of hereditary mucoepithelial dysplasia, a condition of defective expression of cytoskeleton-junctional elements, presents as erythematous mucosa.

WHITE SPONGE NEVUS (CANNON WHITE SPONGE NEVUS)

Clinical Findings

- Usually noted in first 2 decades of life but persist throughout life; may remit and exacerbate
- White-to-gray, folded, painless, edematous, and spongy appearance of buccal mucosa (most common), tongue, labial mucosa, and floor of mouth; may have esophageal and genital involvement (Fig. 2-1)

Etiopathogenesis and Histopathologic Features

This is a rare, autosomal dominant conditions resulting from a mutation of the helical domain on K4 (chromosome 12q) and K13 (chromosome 17q) leading to keratin instability and abnormal tonofilament aggregation.

- Variable parakeratosis, benign epithelial hyperplasia with "spongy appearance" caused by cytoplasmic vacuolation (from glycogen) and not true spongiosis; minimal to no inflammation (Fig. 2-2, *A* and *B*)
- Perinuclear eosinophilic condensations of keratin and dyskeratotic cells *sine qua non* for diagnosis (see Fig. 2-2, *C*); rare cases with epidermolytic hyperkeratosis

Differential Diagnosis

- Leukoedema morsicatio mucosae oris exhibit keratinocytic endema but do not exhibit perinuclear keratin condensations.
- Hereditary benign intraepithelial dyskeratosis (see later) has "cell-within-a-cell" structures.

Management and Prognosis

- No treatment is required usually; some cases respond to antibiotic therapy.

HEREDITARY BENIGN INTRAEPITHELIAL DYSKERATOSIS

Clinical Findings

- Associated with Haliwa Indians in North Carolina and their descendants (usually on East Coast of the United States); diagnosed in first 2 decades of life
- Oral mucosa with thickened painless, diffuse, folded spongy white plaques similar to white sponge nevus
- Eye lesions present as gelatinous plaques on bulbar conjunctiva in perilimbic location

Etiopathogenesis and Histopathologic Features

Hereditary benign intraepithelial dyskeratosis is an autosomal dominant condition resulting from a duplication on chromosome 4q35.

- Hyperparakeratosis and acanthosis; dyskeratotic "tobacco" cells (because of their brown color seen in Papanicolaou stains) in upper epithelium in a typical cell-within-a-cell appearance (Fig. 2-3)

Differential Diagnosis

- White sponge nevus (see earlier) shows perinuclear keratin condensations.
- Darier disease or warty dyskeratoma is acantholytic with dyskeratosis without the cell-within-a-cell appearance.

Management and Prognosis

- No treatment is effective.

DARIER DISEASE (KERATOSIS FOLLICULARIS) AND WARTY DYSKERATOMA

Clinical Findings

- Darier disease characterized by white, painless, keratotic papules (seen in mild disease) or plaques and cobblestoning of the mucosa (seen in more severe disease) in 10% to 50% of patients with skin disease (Fig. 2-4); onset in first and second decade; lesions on palate, gingiva or tongue; skin findings invariably present; up to one third of cases with parotid or submandibular swelling likely because of strictures and obstruction
- Warty dyskeratoma: isolated white, warty papule usually of the palate or gingiva

Etiopathogenesis and Histopathologic Features

Darier disease is an autosomal dominant disorder associated with a mutation of ATP2A2 gene (on chromosome 12q) involved in cytoplasmic calcium transport that is required for proper functioning of desmosomes and keratin formation, resulting in dyscohesion. Warty dyskeratoma is of unknown etiology but has the same histology.

- Often umbilicated/crateriform hyperkeratosis, elongated, slender rete ridges 3 to 8 cells wide, and suprabasilar acantholysis with villous-like projections of connective tissue papillae rimmed by basal cells; dyskeratotic cells with dark nuclei in the form of slender grains (needle-shaped) or *corps ronds* (round) may not be prominent; variable chronic inflammation (Fig. 2-5)

Differential Diagnosis

- Pemphigus shows acantholytic cells, no dyskeratosis, and positive direct immunofluorescence studies.
- Pyostomatitis vegetans shows suprabasilar clefting, no dyskeratosis, and many eosinophils.

Management and Prognosis

- Darier disease is managed with topical steroids, whereas warty dyskeratoma is excised.

Nodular or Tumor-Like Lesions

FORDYCE GRANULES, SEBACEOUS HYPERPLASIA, AND ADENOMA

Clinical Findings

- Fordyce granules: 1 to 3 mm yellowish papules or macules on the posterior buccal mucosa, vermilion of lips, usually bilateral and symmetric, present in 80% of population (Fig. 2-6)
- Sebaceous hyperplasia and adenoma: larger yellowish papules and nodules at same sites as Fordyce granules
- Sebaceous choristoma: usually midline of tongue in area of foramen cecum

Etiopathogenesis and Histopathologic Features

Fordyce granules are considered normal and these can become hyperplastic and adenomatous.

- Fordyce granules: mature sebaceous glands open onto the mucosa via duct; sebocytes have central nuclei and vacuolated cytoplasm; hair and *Demodex folliculorum* have been reported (Fig. 2-7).
- Hyperplasia: at least 15 lobules (this number is somewhat arbitrary); ducts lined by low cuboidal to columnar epithelium (Figs. 2-8 and 2-9).
- Adenoma: proliferation of germinative cells at the periphery of the lobules

Differential Diagnosis

- Salivary gland neoplasms with sebaceous cells are encapsulated tumors with only foci of sebaceous differentiation.

Management and Prognosis

- Excision of sebaceous hyperplasia and adenoma is curative.

CONGENITAL GRANULAR CELL TUMOR (CONGENITAL GRANULAR CELL EPULIS)

Clinical Findings

- Pink, pedunculated mass on the alveolar ridge in newborn; 10:1 female predilection; 3:1 predilection for the maxillary ridge mucosa (Fig. 2-10); synchronous lesions may be present; some regress; rarely manifest on the extragingival sites such as the tongue

Etiopathogenesis and Histopathologic Features

Congenital granular cell tumor is a mesenchymal tumor and exhibits subplasmalemmal dense bodies, pinocytotic vesicles containing precollagenous material, and intracytoplasmic laminin and fibronectin, suggesting myofibroblastic differentiation.

- Sheets of cells with pale, granular cytoplasm, well-defined cell borders and nuclei with dispersed chromatin and small nucleoli; prominent arborizing vessels; S-100 negative but CD68, NK1/C3, and PGP9.5 positive (Fig. 2-11); 40% are neuron-specific enolase (NSE)-positive
- Atrophic epithelium with no pseudoepitheliomatous hyperplasia

Differential Diagnosis

- Conventional granular cell tumor is positive for S-100 protein.
- Primitive polypoid granular cell tumor shares the same immunohistochemical profile.

Management and Prognosis

- Excision is curative.

OSSEOUS AND CARTILAGINOUS CHORISTOMAS

Clinical Findings

- Osseous choristoma: pedunculated mass or nodule usually midline of posterior tongue (>90% of cases) near the foramen cecum; usually in young adults with female predilection (3 to 5:1)
- Cartilaginous choristoma: nodule in lateral tongue (>80% of cases) in adults

Etiopathogenesis and Histopathologic Features

Possible etiologies include metaplastic bone or cartilage formation from trauma, developmental malformation from pluripotent stem cells in the soft tissues, or ossification of branchial arch remnants.

- Osseous choristoma: discrete proliferation of mature lamellar bone is evident (sometimes with mature adipose or hematopoietic tissue) (Fig. 2-12).
- Cartilaginous choristoma: mature hyaline cartilage with spindle cell proliferation or primitive mesenchyme, salivary gland tissue, or bone may be present.

Differential Diagnosis

- Myoepithelioma with abundant bone and cartilage production will show a prominent spindle cell proliferation. (See Benign Salivary Gland Neoplasms in Chapter 16)
- Metaplastic cartilage is often seen in denture-related fibrous hyperplasias in the maxillary vestibule and in the nasopalatine duct area.
- Myositis ossificans shows distinct "zoning" phenomenon with many plump osteoblast-like cells.

Management and Prognosis

- Excision is curative.

GINGIVAL FIBROMATOSIS

Clinical Findings

- Diffuse overgrowth of densely fibrous gingival tissue of the mandible and/or maxilla occurs, usually in the first decade of life during eruption of permanent teeth (Fig. 2-13).
- Localized versions occur especially in area of the maxillary tuberosity, bilaterally.
- Gingival fibromatosis is associated with some syndromes (such as Zimmerman-Laband and Rutherford syndromes); syndromic patients may also be taking medications used to control seizures (e.g., phenytoin) and these can aggravate the gingival hyperplasia.

Etiopathogenesis and Histopathologic Features

The gene for the nonsyndromic, autosomal dominant form is localized to chromosome 2p and inherited in an autosomal dominant or recessive manner. There is increased production and reduced metabolism of collagen and ground substance, possibly because of reduced matrix metalloproteinase activity mediated by transforming growth factor beta-1.

- Proliferation of densely collagenized fibrous tissue in short fascicles with benign, plump, stellate-shaped fibroblasts; generally paucicellular (Fig. 2-14)

Differential Diagnosis

- Inherited systemic hyalinosis (mild form formerly known as juvenile hyaline fibromatosis and more severe form, infantile systemic hyalinosis) is an autosomal recessive condition and manifests with fibrous skin nodules, bone lesions, and joint contractures; gingival overgrowths consist of densely hyalinized, paucicellular stromal deposits that resemble chondroid material or amyloid; there is a mutation in the ANTXR2 gene (formerly capillary morphogenesis factor-2 gene) mapped to chromosome 4q21 (Fig. 2-15).
- Myofibromatosis usually is more cellular with longer sweeping fascicles of collagen; clinically, lesions are discrete.

Management and Prognosis

- Excision and recontouring help esthetics; maintenance of good oral hygiene (with use of antimicrobial oral rinses) reduces severity of recurrence.

GASTROINTESTINAL AND BRAIN HETEROTOPIAS

Clinical Findings

- Mass in the tongue or floor of mouth in infants or neonates, often in the midline, near the foramen cecum associated with sinus tracts

Etiopathogenesis and Histopathologic Features

Heterotopias are likely caused by entrapped or displaced gastrointestinal tissues.

- Gastrointestinal heterotopia: lined by epithelium typical for the cardiac, fundic, or pyloric regions of the stomach with parietal and Paneth cells; some are lined by colonic and/or ciliated epithelium; pancreatic tissue may be identified (Fig. 2-16)
- Brain heterotopia: astrocytes, oligodendrocytes, ependymal tissue, choroid plexus–like tissue and, rarely, neuronal tissue identified (Fig. 2-17)

Management and Prognosis

- Excision is curative.

LYMPHANGIOMA OF THE ALVEOLAR RIDGE IN NEONATES

Clinical Findings

- Four percent of infants, almost exclusively black infants
- Dome-shaped, 3- to 4-mm, bluish, fluid-filled nodules in the posterior maxillary and mandibular alveolar ridge; usually multiple lesions present

Etiopathogenesis and Histopathologic Features

Etiopathogenesis is unknown and is more likely to represent lympathic ectasia.

- Typical endothelium-lined spaces filled with amorphous eosinophilic material; may see odontogenic rests

Differential Diagnosis

- Indistinguishable from lymphatic malformation or lymphangioma circumscriptum found in older patients

Management and Prognosis

- No treatment; resolves by 6 months of age

LINGUAL THYROID

Clinical Findings

- Occurs in first to second decade, and fifth to sixth decade with female predilection (7:1); can lead to dysphagia and dyspnea; up to 25% of patients are hypothyroid
- Dectable soft mass between foramen cecum and epiglottis in midline posterior to the circumvallate papillae

Etiopathogenesis and Histopathologic Features

This may represent remnants of thyroid tissue or an entire undescended thyroid; nuclear scans show presence of thyroid tissue.

- Mature or embryonic thyroid epithelium with microfollicular, macrofollicular, or adenomatous changes (Fig. 2-18); may be associated with thyroglossal duct

Management and Prognosis

- If this represents undescended thyroid, removal leads to hypothyroidism and requires repletion.
- Follicular, papillary, and medullary carcinomas have been reported.

LEIOMYOMATOUS HAMARTOMA

Clinical Features

- Soft, painless polypoid mass usually on the tongue and anterior maxilla/palate (area of the nasopalatine foramen)

Etiopathogenesis and Histopathologic Features

- Nonencapsulated proliferation of fusiform and spindle smooth muscle cells that express HHF-35, smooth muscle actin, and desmin but not S-100 protein (Fig. 2-19)

Management and Prognosis

- Excision is curative.

Cystic Lesions

ORAL LYMPHOEPITHELIAL CYST (BENIGN LYMPHOEPITHELIAL CYST)

Clinical Findings

- Usually occurs in third to fourth decade; yellowish, painless, soft nodule of the soft palate or tonsillar pillars, floor of mouth, or posterior tongue; filled with cheesy, keratinaceous material (Fig. 2-20, *A*)

Etiopathogenesis and Histopathologic Features

Lymphoepithelial cysts may arise from entrapped embryonic epithelial remnants of surface epithelium or salivary ducts, or from blocked crypts of lingual or ectopic tonsils. They are histologically indistinguishable from parotid lymphoepithelial cysts often seen in patients with HIV infection (see Fig. 2-20, *B*).

- Lining is composed of parakeratotic, uniformly thin (5 to 10 cells) stratified squamous epithelium often with prominent lymphocyte exocytosis, surrounded partially or completely by a mantle of lymphocytes that may exhibit germinal centers; lumen filled with keratinaceous material; infrequently mucous cells or respiratory epithelium is present (Figs. 2-21 and 2-22).

Differential Diagnosis

- Hyperplastic lingual tonsils are not as obviously cystic, although blockage of the crypt opening often leads to retention of secretions, and the two may become indistinguishable (Figs. 2-23 and 2-24).
- Salivary duct cysts do not exhibit a lymphocytic mantle.
- Epithelial inclusion cysts are orthokeratotic and do not exhibit a lymphocytic mantle.

Management and Prognosis

- Excision is curative.

EPIDERMOID (EPITHELIAL INCLUSION) AND DERMOID CYSTS

Clinical Findings

- Dome-shaped, doughy, painless yellow nodules and masses, usually in the midline of floor of mouth in children and young adults; may be congenital; often located above the geniohyoid or between the geniohyoid and mylohyoid; slight male predilection (3:1); rare cases on the buccal mucosa (Fig. 2-25)

Etiopathogenesis and Histopathologic Features

The epithelium arises from displaced epithelium or entrapped epithelial rests during embryonic fusion. It is similar to the epidermal inclusion cyst of the skin.

- Epidermoid cyst (most common): lined by orthokeratinized stratified squamous epithelium 5 to 10 cells thick with lumen filled with keratin (Fig. 2-26); rupture results in foreign body granulomatous reaction
- Dermoid cyst: similar to epidermoid cyst but contains hair follicles, sebaceous glands, or eccrine structures (Fig. 2-27)

Differential Diagnosis

- If tissue from all three germ layers is present, diagnosis is teratoid cyst.
- Gingival cyst of the newborn has similar histology but is located on the gingiva; gingival cyst of the adult is infrequently keratinizing.
- Dermoid tumors are solid tumors usually located on the soft palate, covered by skin with adnexal structures—often with a mesodermal component (known as a "hairy polyp").

Management and Prognosis

- Excision is curative.

PALATAL AND GINGIVAL CYSTS OF THE NEONATE

Clinical Findings

- Yellowish milia-like papules on the midline of the palate, junction of hard and soft palate, or gingiva in newborn with a frequency of 10% to 70% (Fig. 2-28).

Etiopathogenesis and Histapathologic Features

Cysts in the midline of the palate (Epstein pearls) and gingiva (original Bohn nodules) are likely epithelial inclusion cysts formed from entrapped embryonic epithelium during fusion of palatal shelves and dental lamina rests, respectively. The ones at the junction of the hard and soft palate, sometimes also referred to as Bohn nodules are likely caused by blocked excretory salivary ducts, rather than use eponyms, it is preferable to refer to these as palatal or gingival cysts of the neonate.

- Simple cysts lined by three to five layers of stratified squamous epithelium, often filled with keratin

Management and Prognosis

- Biopsy not indicated because they usually exteriorize on their own.

CYST OF THE INCISIVE PAPILLA

Clinical Findings

- Swelling, usually less than 1 cm, of the incisive papilla without underlying bone involvement (Fig. 2-29)

Etiopathogenesis and Histopathologic Features

Epithelium likely derives from rests of the nasopalatine duct within soft tissues.

- Cyst lined by ciliated, pseudostratified columnar epithelium with mucous cells, flattened low cuboid epithelium, or two to five layers of nonkeratinized stratified squamous epithelium; neurovascular bundles may or may not be present; minimal inflammation (Figs. 2-30 and 2-31)

Differential Diagnosis

- Nasopalatine duct cyst has similar histology but is present within bone (see Chapter 16).

Management and Prognosis

- Excision is curative.

NASOLABIAL CYST (NASOALVEOLAR CYST)

Clinical Findings

- A 2:1 female predilection in patients in the fifth decade; soft, painless fluctuant swelling of the upper labial mucosa in the area of the nasolabial fold

Etiopathogenesis and Histopathologic Features

Epithelium is derived from remnants of the nasolacrimal duct.

- Cyst lined by low cuboidal to columnar ciliated epithelium with mucous cells, nonkeratinized stratified squamous epithelium, or a mixture of both (Fig. 2-32)

Differential Diagnosis

- Epithelial inclusion cysts of the skin are keratinizing.

Management and Prognosis

- Excision is curative.

3 Noninfectious Papillary Lesions

CHAPTER CONTENTS

INFLAMMATORY PAPILLARY HYPERPLASIA OF THE PALATE

Clinical Findings

- Papillary hyperplasia of the palate usually occurs in adults wearing dentures; it is occasionally seen in patients with high-arched palates and mouth-breathing habit (with adenoidal facies); may be sensitive, especially if associated with erythematous candidiasis, because denture may act as a fomite; dryness from mouth-breathing also predisposes to candidiasis (Fig. 3-1).
- Pebbly excrescences appear on the palatal vault in a diffuse, symmetric distribution.
- Papillary lesions associated with human papillomavirus infection are discussed in Chapter 4.

Etiopathogenesis and Histopathologic Features

Chronic irritation from the denture or from mouth-breathing leads to reactive hyperplasia of tissues.

- There is proliferation of fibrous tissue in nodules with variable lymphoplasmacytic infiltrate; overlying epithelium may be hyperplastic and exhibit spongiosis and leukocyte exocytosis; pseudoepitheliomatous hyperplasia may be seen (Figs. 3-2 to 3-4).
- Presence of spongiotic pustules should always raise suspicion for candidiasis and a periodic acid–Schiff (PAS) stain with diastase should be performed.

Differential Diagnosis

- Inflamed squamous papilloma is usually single and pedunculated.

Management and Prognosis

- Excise or ablate lesions with scalpel or laser and reline or remake denture; lesions may recur if denture continues to fit poorly.
- Treat candidiasis with topical antifungals (e.g., nystatin or clotrimazole troches) or systemic therapy (e.g., fluconazole).

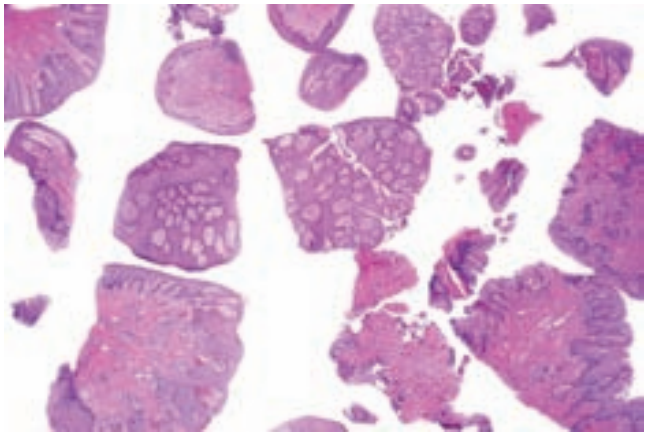

FIGURE 3-4. Inflammatory papillary hyperplasia, curetted specimen.

VERRUCIFORM XANTHOMA

Clinical Findings

- Discrete and localized nontender plaque with a pebbly, warty appearance; may appear yellowish or mucosa colored; located on the keratinized tissues of the hard palate, gingiva, or tongue in adults (Fig. 3-5)
- Associated with diseases characterized by damage to the epithelium such as lichen planus, pemphigus vulgaris, epidermolysis bullosa, and chronic graft-versus-host disease

Etiopathogenesis and Histopathologic Features

This is a reactive lesion believed to be a histiocytic response to products of epithelial breakdown.

- Benign papillary proliferation of stratified squamous epithelium is seen with rete ridges, generally of the same length and confluent at the bases (Figs. 3-6, *A* and 3-7, *A*); infrequently, lesions have a flat surface (Fig. 3-8, *A*).
- Hyperparakeratosis with bright orange-eosinophilic hue, parakeratin plugs, and keratin squames on the surface and within crypts; neutrophilic exocytosis and spongiosis often present; foamy macrophages (positive for CD68) fill the lamina propria (Fig. 3-9; see Figs. 3-6 to 3-8); when inflamed, keratin may be minimal (Fig. 3-10).

Differential Diagnosis

- Verrucous hyperplasia (a dysplastic lesion) will show significant cytologic atypia, bulbous rete ridges, and usually an endophytic growth pattern.

Management and Prognosis

- Excision is treatment of choice; lesion tends not to recur even if incompletely excised.

JUVENILE LOCALIZED SPONGIOTIC GINGIVAL HYPERPLASIA

Clinical Findings

- Greater than 90% occur between 5 to 15 years of age mostly on the maxillary (84%) anterior facial gingiva; 15% of patients have orthodontic hardware on the teeth.
- It appears as an erythematous, often pebbly, easily bleeding, nontender plaque, less than 1 cm, on the marginal gingiva; may be multifocal (Fig. 3-11).

Etiopathogenesis and Histopathologic Features

This is a reactive lesion likely related to trauma and local irritation; unclear if the epithelial proliferation is crevicular or junctional in nature.

- Benign usually pedunculated, papillary (may be subtle) proliferation of nonkeratinized stratified squamous epithelium; prominent spongiosis and leukocyte exocytosis; dilated vessels with variable numbers of plasma cells (Fig. 3-12)
- Epithelium positive for CK19

Differential Diagnosis

- Lesions may represent inflamed squamous papilloma (gingiva is a common location for this and age group is also supportive) (Fig. 3-13).

Management and Prognosis

- Excision is treatment of choice and lesion is unlikely to recur.

4 Bacterial, Viral, Fungal, and Other Infectious Conditions

CHAPTER CONTENTS

Any infection that occurs in any other part of the body may manifest in the mouth, including mycobacterial, treponemal, and bartonellal infections, although they are uncommon and rarely occur initially in the mouth. In many parts of the world, mycobacterial and syphilitic infections are on the rise. Polymicrobial bacterial infections in the mouth are the most common and are generally not subject to biopsy because most of these are related to dental caries and periodontal infections. Actinomycosis is one bacterial infection that is seen on biopsy with some frequency.

ACTINOMYCOSIS

There are five common areas of involvement—cervicofacial, pulmonary, ileocecal, genitourinary, and central nervous system. The less well known and yet fairly common infection involving the jawbones and oral soft tissues is discussed here.

Clinical Findings

- Actinomycosis most often manifests as a periapical radiolucency, painful or painless, in a root canal–treated or grossly carious tooth (Fig. 4-1, *A*); it may also be associated with impacted teeth, periodontitis, or around dental implants; 80% of cases are asymptomatic; approximately 20% involve the soft tissues only; mandibular tooth infection may lead to cutaneous fistula (see Fig. 4-1, *B*).
- Sinus tract (known as gingival parulis) and suppuration are always present; yellowish "sulfur granules" representing masses of bacteria may be noted during biopsy.
- Presence of actinomycetes colonies in the absence of actinomycotic infection may predispose patients to obstructive tonsillar hypertrophy.

Etiopathogenesis and Histopathologic Features

Actinomyces are gram-positive microaerophilic, obligate, or facultative filamentous bacteria. There are several species, such as *A. odontolyticus, A. israelii, A. naeslundii, A. gerencseriae,* and *A. viscosus.* They cause suppurative lesions and enter the bone through a preexisting sinus tract or through a carious tooth.

- Abundant granulation tissue with abscesses, chronic inflammation; masses of sulfur granules are composed of a round-to-ovoid masses of filamentous bacteria with a peripheral eosinophilic rim often with eosinophilic radiating "clubs" or fringe and clinging neutrophils (Figs. 4-2, 4-3, *A-C*); bacteria gram-positive and argyrophilic (see Fig. 4-3, *D, E*); concomitant apical radicular or dentigerous cyst or periapical granuloma often present
- Clumps of actinomycetes alone without the eosinophilic fringe not sufficient for the diagnosis (see later)

Differential Diagnosis

- Actinomycotic colonies are a common component of dental plaque and do not represent actinomycosis in the absence of suppuration and clinical signs (see Chapter 7).
- Masses of actinomycotic organisms are often found on the surface of exposed bony sequestra, especially in bisphosphonate-associated osteonecrosis of the jaws (see Chapter 16).

Management and Prognosis

- Curettage, 2 to 3 weeks of antibiotics (e.g., amoxicillin, doxycycline, or clindamycin), and removal of the original source of infection (such as carious or impacted tooth) is curative; prolonged antibiotic therapy is not indicated for conventional periapical actinomycosis.

Periapical actinomycosis. **A,** Periapical granuloma and sulfur granule. **B,** Sulfur granule with typical radiating morphology and suppuration. **C,** Sulfur granule (Brown and Brenn stain). **D,** Sulfur granule containing numerous gram-positive filamentous bacteria. **E,** Sulfur granule containing slender argyrophilic filaments (methenamine silver stain).

CANDIDIASIS (CANDIDOSIS)

This is the most common fungal infection in the mouth.

Clinical Findings

- Thrush or pseudomembranous candidiasis: curdy white papules and plaques that may or may not wipe off; usually sore or sensitive and has erythematous areas (Fig. 4-4, *A* and *B*)
- Erythematous candidiasis: sensitive erythematous area often outlined by the shape of a denture; also as linear erythematous gingivitis in patients with HIV/AIDS (see Fig. 4-4, *C* and *D*)
- Angular cheilitis: pain, cracking, fissuring, and maceration of corners of mouth (usually bilateral); seen in denture wearers where dentures do not adequately support soft tissues; also in vitamin B_{12} and iron deficiencies (see Fig. 4-4, *E*)
- Hyperplastic candidiasis: white plaques seen in mucocutaneous disease, endocrinopathies, and immunosuppression; common on the commissures bilaterally; often associated with hairy leukoplakia (see later)
- Median rhomboid glossitis: erythematous, ovoid, or rhomboid raised area of the midline dorsum of tongue anterior to the circumvallate papillae (see Fig. 4-4, *F*)
- Candidiasis on the tongue dorsum: often associated with concomitant "kissing" lesions on the palate (see Fig. 4-4, *G* and *H*)

Etiopathogenesis and Histopathologic Features

Lesions are caused by *Candida albicans* or other species when the flora in the mouth is altered because of hyposalivation, use of antibiotics or corticosteroids, and immunosuppression. Because *Candida* is a commensal in approximately 20% of the population, a positive culture in and of itself is not diagnostic for candidiasis. Scraping the lesion and use of either potassium hydroxide or standard cytology stains to identify hyphae is diagnostic, as is a biopsy.

- Epithelial hyperplasia (often psoriasiform) with parakeratosis, neutrophilic exocytosis and spongiotic pustules, reactive epithelial atypia, vascular ectasia, and variable lymphocytic infiltrates (Fig. 4-5, *A-C*); candidal hyphae and/or conidia seen in the periodic acid–Schiff (PAS) stain with diastase digestion or methenamine silver stain (see Fig. 4-5, *A inset*); possible epithelial atrophy noted (Fig. 4-6)
- Median rhomboid glossitis: loss of filiform papillae and presence of median raphe, normal hyalinized band in the midline of tongue, sometimes misdiagnosed as amyloid deposition (Fig. 4-7)

Differential Diagnosis

- Epithelial dysplasia with secondary candidiasis exhibits significant epithelial atypia and may be difficult to differentiate from candidiasis with reactive atypia (see Fig. 4-6, *B*); however, effective treatment completely resolves candidiasis without dysplasia.
- Spongiotic pustules are also seen in:
  - Benign migratory glossitis/stomatitis
  - Edge of ulcer or erosions
  - Oral psoriasis (see relevant sections)
- *Geotrichum candidum* (causing geotrichosis) form short septate hyphae.

Management and Prognosis

- See Appendix B.
- *Staphylococcus aureus* is present in up to 30% of patients with angular cheilitis; concomitant topical erythromycin is helpful if lesions are recalcitrant.

INFECTIOUS GRANULOMATOUS INFLAMMATION

Clinical Findings

- Concomitant systemic or skin involvement is usually noted and history is very important in the diagnosis.
- Ulcerated and indurated, granular, vegetating nodules of the palate and gingiva are common oral presentations, and there is usually concomitant lung, nodal, and skin disease; immunocompromised patients are particularly susceptible to disseminated disease.
- Coccidioidomycosis caused by *Coccidioides immitis* is endemic in California and the southwest United States.
- Histoplasmosis caused by *Histoplasma capsulatum* is endemic to the Ohio-Mississippi Valley and is found in the soil and in bird and bat droppings; patients taking tumor necrosis factor-α inhibitors are prone to contracting this infection, as well as coccidioidomycosis in endemic areas.
- Paracoccidioidomycosis caused by *Paracoccidioides brasiliensis*, a soil saprophyte, is common in South America where 80% to 90% of cases are chronic (Fig. 4-8).
- Phycomycoses (order Mucorales, genera *Rhizopus, Absidia, Mucor, and Rhizomucor*) and aspergillosis (*Aspergillus fumigatum* or *A. flavus*) appear black, necrotic and/or fungating, resembling malignancy; rhinocerebral phycomycosis is increasing in frequency and is often seen in patients with diabetes (especially if ketoacidotic), neutropenia, malignancy, and post–organ transplantation; mortality rate is 60% to 90%; aspergillosis appears similar but tends to affect immunocompromised patients (such as those with leukemia) rather than those with diabetes; both primarily affect the palate and maxilla, and vascular involvement leads to necrosis.

Etiopathogenesis and Histopathologic Features

- Coccidioidomycosis: pseudoepitheliomatous hyperplasia with granulomatous inflammation and budding organisms (Fig. 4-9)
- Histoplasmosis is a granulomatous inflammation, sometimes with necrosis (Fig. 4-10).
- Zygomycosis is a necrotic lesion with hyphal forms invading blood vessels; ribbon-like organisms, with right-angle branching (Fig. 4-11) are evident.
- Aspergillosis is similar to zygomycosis but organisms are slender and show acute-angle branching (Fig. 4-12); must be differentiated from mycetoma or "fungus ball" within the sinus that does not invade the soft tissues (Fig. 4-13).
- Identification of the organism using immunohistochemical stains; correlation with the clinical presentation, serology, and other tests are crucial if no organisms are found.

Differential Diagnosis

- A search for foreign bodies must always be undertaken.
- Sarcoidosis produces nonnecrotizing granulomas, as does Crohn disease.

Management

- Appropriate antimicrobial therapy such as with itraconazole, voriconazole, posaconazole, and amphotericin B

HERPESVIRUS INFECTIONS

Table 4-1 shows the eight herpesviruses pathogenic in humans. All herpesviruses establish latency after a primary infection that may be subclinical or may exhibit only mild constitutional symptoms. Most adults in the United States are seropositive for many of the herpesviruses.

HERPES SIMPLEX VIRUS INFECTION

Clinical Findings

- Primary herpetic gingivostomatitis: acute onset of painful coalescent ulcers on any mucosal surface but frequently on the labial mucosa, tongue, and gingiva; associated with viral prodrome, malaise, and fever; may be herpes simplex virus (HSV)-1 or -2; usually in children and young adults (Fig. 4-14, *A* and *B*)
- Recrudescent infection in healthy hosts: herpes labialis (e.g., fever blisters or cold sores) on the lip or on the keratinized mucosa of the hard palate and attached gingiva (see Fig. 4-14, *C-E*); painful, coalescent 2- to 3-mm ulcers; often induced by injury (e.g., sunburn) or trauma (e.g., after dental procedures)
- Recrudescent infection in immunocompromised hosts: ulcers anywhere on the oral mucosa may appear aphthous-like if on the nonkeratinized mucosa; often biopsied (see Fig. 4-14, *F*)
- Careful interpretation of positive cultures, because asymptomatic shedding (induced by trauma, illness, or stress) is a frequent occurrence
- At least 50% of cases of erythema multiforme are induced by HSV reactivation.

Etiopathogenesis and Histopathologic Features

- HSV and varicella zoster virus are DNA viruses that are destructive to epithelial cells; latency is established in sensory ganglia and periphery at mucosa.
- Multinucleated giant epithelial cells at the edge of the ulcer exhibit "nuclear molding" and acute and chronic inflammation (Fig. 4-15); nuclei contain "ground glass" amphophillic Cowdry inclusions.
- A biopsy of only the center of the ulcer without epithelium may not show viral inclusions and cannot be presumed negative for herpes simplex infection; it should be viewed as inadequate for diagnosis.

Differential Diagnosis

- Varicella zoster virus has a similar cytopathic effect but clinically tends to be unilateral; culture and immunohistochemical studies differentiate between the two (Fig. 4-16).
- Inflammatory reactions may contain multinucleated giant epithelial cells, but these have dispersed chromatin, no Cowdry inclusions, prominent nucleoli, and abundant cytoplasm without nuclear molding.

Management and Prognosis

- Primary infections or recrudescent infections in immunocompromised patients: hydration, supportive care, pain control, systemic acyclovir (low bioavailability), valacyclovir, or famciclovir
- Herpes labialis: 1- or 2-day treatment with valacyclovir or famciclovir, topical acyclovir, penciclovir, or docosanol; use of sunscreen to prevent recrudescent herpes labialis caused by sun damage

TABLE 4-1 Herpesvirus Infections

Herpesvirus Type	Disease Manifestation in the Oral Cavity
HHV-1 HSV-1 Alpha virus	Primary herpetic gingivostomatitis or genital herpes; recrudescent herpes stomatitis or herpes labialis; genital herpes
HHV-2 HSV-2 Alpha virus	Although usually found on skin and mucosa below the waist, may also be found in the mouth with lesions identical to those of HSV-1
HHV-3 Varicella-zoster virus Alpha virus	Primary infection is chickenpox; recrudescent infection is facial or oral shingles along distribution of trigeminal nerve, usually unilateral; skin shingles
HHV-4 Epstein-Barr virus Gamma virus	Hairy leukoplakia in patients with HIV/AIDS, organ transplant recipients or other immunocompromised host Infectious mononucleosis, Burkitt lymphoma, nasopharyngeal carcinoma, central nervous system lymphoma, posttransplantation lymphoproliferative disorder, Hodgkin lymphoma Epstein-Barr virus–positive mucocutaneous ulcer in immunosuppressed host
HHV-5 Cytomegalovirus Beta virus	Oral ulcers, penetrating; may be bystander noted in other ulcerative lesions Infectious mononucleosis–like syndrome, retinitis, gastroenteritis, hepatitis, pneumonitis
HHV-6 Beta virus	No oral findings Roseola infantum, exanthema subitum
HHV-7 Beta virus	No oral findings Roseola infantum, exanthema subitum
HHV-8 Kaposi sarcoma herpesvirus Gamma virus	Oral, skin and visceral Kaposi sarcoma Primary effusion lymphoma, multicentric Castleman disease

HHV, human herpes virus; HSV, herpes simplex virus; HIV/AIDS, human immunodeficiency virus/acquired immunodeficiency syndrome.

FIGURE 4-14. Herpes simplex virus. **A,** Primary infection with coalescent ulcers on tongue dorsum. **B,** Same patient as in **A** with ulcers on the nonkeratinized labial mucosa and marginal gingiva. **C,** Recrudescent herpes simplex virus: herpes labialis in immunocompetent host. **D,** Recrudescent herpes simplex on the attached gingiva in immunocompetent host. **E,** Recrudescent herpes simplex on the hard palatal mucosa. **F,** Recrudescent herpes simplex virus ulcer of the ventral tongue and skin in a patient with cancer.

HAIRY LEUKOPLAKIA

Hairy leukoplakia is highly predictive of positive HIV status. The term *leukoplakia* as used in this context does not connote any tendency to dysplasia or malignancy.

Clinical Findings

- White, painless, linear, or plaquelike lesion usually of the lateral border of tongue; classically, white lines run perpendicular to the long axis of the tongue (Fig. 4-17)
- Seen in immunocompromised individuals, especially those with HIV/AIDS with low CD4 count and in organ transplant recipients; rare cases have been reported in healthy patients

Etiopathogenesis and Histopathologic Features

Entry of virus from peripheral blood lymphocytes (reservoir for the virus) into the epithelium, followed by reactivation of the virus, leads to appearance of hairy leukoplakia.

- Variable hyperparakeratosis with or without bacterial colonization (factitial keratosis); candidal hyphae and/or conidia present—often in the absence of spongiotic pustules

- Sharp demarcation of parakeratin from the subjacent ballooned superficial keratinocytes; virally infected cells show "beading" of chromatin along nuclear membrane; Cowdry inclusion ("ground glass" amphophilic nuclear mass consisting of virions) fills the center of the nucleus (Figs. 4-18, *A-C* and 4-19); such findings are also seen in exfoliative cytology.
- Confirmation is nuclear positivity by in situ hybridization for Epstein-Barr encoded RNA (EBER), Epstein-Barr nucleic acid (EBNA), and latent membrane protein (LMP) (see Fig. 4-18, *D*).
- Electron microscopy confirms herpesvirus-sized particles in the center of the nucleus with chromatin margination at periphery (Fig. 4-20).

Differential Diagnosis

- Factitial/frictional keratoses from bite trauma do not show chromatin margination and are negative for Epstein-Barr virus (EBV) by in situ hybridization (Fig. 4-21).

Management and Prognosis

- Adjustment of antiretroviral therapy or reduction of immunosuppressive therapy if post–organ transplantation may resolve lesions; candidiasis should be treated.
- Cases may resolve with a combination of topical antiherpetic medications (such as 1% penciclovir or 5% acyclovir cream/ointment) and 25% podophyllin resin.
- Treatment with valacyclovir reduces recurrence of disease in 67% of patients.
- Hairy leukoplakia may be first indication of HIV-positive status.

CYTOMEGALOVIRUS INFECTION

Clinical Findings

- Large, usually solitary, painful ulcer on the oral mucosa (Fig. 4-22) that is often nonspecific appearing; antigenemia may be present
- Seen in immunocompromised individuals, especially those with HIV/AIDS or who are organ transplant recipients

Etiopathogenesis and Histopathologic Features

Cytomegalovirus infects monocytes, endothelial cells, and fibroblasts in the deep lamina propria; it may also represent an incidental finding ("passenger") in an ulcer caused by another agent such as herpes simplex virus and may be seen in clinically normal skin; latency is established within endothelial cells, T cells, monocytes, and stromal cells.

- Mucosal ulceration; large, ballooned cells within the endothelium or mesenchymal cells in the connective tissue; "owl-eye" nuclei with prominent nucleoli (Fig. 4-23); dark pink granules present in cytoplasm (Fig. 4-24, *A-C*); confirmation with in situ hybridization (see Fig. 4-24, *D*); biopsies must be of sufficient depth for this condition to be adequately ruled out
- Presence of antigenemia alone not sufficient for the diagnosis

Differential Diagnosis

- EBV-associated mucocutaneous ulcers contain a polymorphous infiltrate characterized by atypical Hodgkin-like cells or Reed-Sternberg–like cells with background B cells that are CD30 and EBER positive, as well as many T cells; some cases show clonal immunoglobulin gene rearrangement and others show clonal and restricted T cell patterns; some lesions regress and others relapse and remit.

Management and Prognosis

- Ganciclovir or valganciclovir are the treatments of choice.
- Immunosuppressive regimens are reduced.

HUMAN PAPILLOMAVIRUS–RELATED BENIGN LESIONS

Squamous papilloma, verruca vulgaris, condyloma acuminatum, and Heck disease are be discussed together because of similarities in clinical presentation and histopathology.

Clinical Findings

- Painless, exophytic, papillary/verrucous, white or pink, sessile or pedunculated growths appear on the mucosa usually in young patients.
- Squamous papillomas are often seen on the soft palate or tongue, white or pink; verruca vulgaris is often on the gingiva, lips, and palate and is almost always white (Fig. 4-25, *A* and *B*)
- Condylomata are single or multiple, papular or papillary, and often seen in immunocompromised hosts (Fig. 4-25, *C-E*)
- Lesions in Heck disease are papular and multiple, often seen in the young (first and second decade) living in crowded conditions in South and Central America with a prevalence of up to 13%; it is also common in Africa, the middle East, in patients with HIV/AIDS, and sporadically in North America (see Fig. 4-25, *F*)

Etiopathogenesis, Histopathologic Features, and Differential Diagnosis

These are related to human papillomavirus infection; in situ hybridization and polymerase chain reaction (PCR) studies to subtype the viruses have allowed these to be characterized more accurately.

- See Table 4-2 and Figures 4-26 to 4-36.

Differential Diagnosis

- Acanthosis nigricans has similar histology to squamous papilloma or condyloma without involvement by human papillomavirus; patients have visceral malignancy (Fig. 4-37).

Management and Prognosis

- Excision is the treatment of choice if lesions are solitary; viral particles have been identified in laser plumes.
- Imiquimod may be useful for vermilion lesions, but it is difficult to keep localized for intraoral applications.

TABLE 4-2 Histopathologic Features and Differential Diagnosis for Squamous Papilloma, Verruca Vulgaris, and Condyloma Acuminatum

Condition	HPV Subtype*	Histopathologic Features	Differential Diagnosis
Squamous papilloma (see Figs. 4-25 to 4-29)	6, 11	Papillary epithelial proliferation in thin ribbons with variable keratosis Soft palate and ventral tongue lesions may show prominent keratinocyte edema with minimal keratin; inflammation often leads to spongiosus and loss of keratin Basal cell hyperplasia often present; koilocytes not always present Fibrovascular cores edematous or hyalinized	Giant cell fibroma has stellate-shaped, giant and multinucleated fibroblast-like cells Papillary epithelial dysplasia exhibits significant cytologic atypia that is not reactive in nature
Verruca vulgaris (see Figs. 4-30 to 4-32)	1, 2, 4, 57	Papillary epithelial proliferation with thick orthokeratin, large kerato-hyaline granules and axial inclination of peripheral rete ridges Koilocytes usually present Inflammation may lead to significant reactive atypia, parakeratosis, and dyskeratosis (especially lip and cutaneous lesions)	Irritated seborrheic keratosis may look similar but with more basaloid cells Inverted follicular keratosis tends to follow orientation of hair follicle
Condyloma acuminatum (see Figs. 4-33 to 4-35)	6, 11	Papillary form—papillary epithelial proliferation with little keratin and large bulbous rete ridges †Koilocytes always seen; basal cell hyperplasia often present Papular form—epithelial hyperplasia without papillary features forming bulbous rete ridges Koilocytes and mitosoid bodies (karyorrhectic cells with coarse, fragmented chromatin) often present	Verrucous hyperplasia is broad-based with marked hyperkeratosis and bulbous rete ridges with variable cytologic atypia/dysplasia Verrucous carcinoma has an endophytic as well as exophytic growth pattern and is hyperparakeratotic Papular form is indistinguishable from Heck disease without HPV subtyping
Heck disease (see Fig. 4-36)	13, 32, 55	Similar to papular form of condyloma acuminatum (see earlier)	Indistinguishable from condyloma acuminatum without HPV subtyping

*Not seen in every case.
†Koilocytes exhibit irregular, twisted nuclear outlines and nuclear hyperchromatism; perinuclear halos alone are not sufficient for the diagnosis.
HPV, human papillomavirus.

SYPHILIS

Clinical Findings

- A resurgence of this condition within the past 2 decades has been noted, especially in men who have sex with men.
- Primary lesion (chancre) occurs within 2 to 8 weeks at site of inoculation, and the most common extragenital site is the mouth, where it appears as a painless ulcer (Fig. 4-38, *A*).
- Secondary syphilis occurs within 2 to 12 weeks as a result of hematogenous spread and manifests as grayish plaques in the mouth, usually soft palate and tongue ("mucous patch") and an erythematous skin rash mimicking other conditions (see Fig. 4-38, *B*); condyloma latum occurs on the skin and genitalia.
- In one third of patients, untreated syphilis results in tertiary lesions that are granulomatous (gumma); syphilitic endarteritis of organs results in organ-specific disease.
- Congenital syphilis is typified by deafness, notched incisors, "mulberry molars," rhagades, and interstitial keratitis.

Etiopathogenesis and Histopathologic Features

The spirochete responsible for this sexually transmitted disease is *Treponema pallidum*.

- Primary and secondary lesions: epithelium exhibits spongiosis and leukocyte exocytosis and may be hyperplastic or atrophic; lymphoplasmacytic infiltrate in the lamina propria in a subepithelial band and around blood vessels that may show endarteritis (Fig. 4-39, *A-D*); thin, threadlike, "cork-screw" organisms can be identified with Warthin-Starry, modified Steiner, or Dieterle stain, or by immunohistochemistry (see Fig. 4-39, *E*).
- Tertiary lesions consist of granulomatous inflammation that does not usually show the presence of the organism, except with PCR.
- Screening tests that evaluate for the presence of antibodies include the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin tests; confirmation is achieved with fluorescent treponemal antibody-absorption test, *Treponema pallidum* particle agglutination assay, microhemagglutination, or PCR; other tests include dark-field microscopy.

Differential Diagnosis

- Identification of the organism is the key to diagnosis because the mucosal inflammatory lesion appears nonspecific.

Management

- Intramuscular penicillin G is the treatment of choice; tetracycline, doxycycline, and azithromycin are effective.

5 Fibrous, Gingival, Lipocytic, and Miscellaneous Tumors

CHAPTER CONTENTS

Fibrous Lesions

FIBROMA ("BITE" OR "IRRITATION" FIBROMA, FIBROEPITHELIAL OR FIBROVASCULAR POLYP) AND GIANT CELL FIBROMA

Clinical Findings

- Dome-shaped nodule or papule; may be white/keratotic, mucosa-colored or ulcerated and is seen in areas readily traumatized by biting (i.e., buccal mucosa, lateral tongue, and lower labial mucosa) or on gingiva (where plaque accumulates) (Fig. 5-1, *A-D*).
- Variant giant cell fibroma has a papillary surface and is usually located on gingiva or tongue (see Fig. 5-1, *E*).
- Sclerotic fibromas may be seen as focal sporadic lesions or in patients with tuberous sclerosis, associated with loss of heterozygosity of the PTEN gene.

Etiopathogenesis and Histopathologic Features

Fibroma is a reactive fibrosis and scarring (similar to a hypertrophic scar on the skin) from bite trauma and is not a true neoplasm.

- Nodular proliferation of fibrous tissue is associated with variable vascularity, hyperparakeratosis or orthokeratosis, ulceration, inflammation, epithelial hyperplasia, or atrophy (Figs. 5-2 and 5-3); variable myxoid/mucinous change (Fig. 5-4); or entrapment of muscle (Fig. 5-5).
- Sclerotic fibroma (also called storiform collagenoma) has dense, hyalinized bands of keloidal collagen with a slight storiform pattern and stellate and fusiform fibroblasts with clefts between collagen fibers; lesions are occasionally positive for factor XIIIa and CD34 (Fig. 5-6).
- Giant cell fibroma exhibits papillary surface, epithelial hyperplasia forming spiky rete ridges; giant,

stellate, multinucleated fibroblast-like cells that sometimes show cytoplasmic positivity for smooth muscle actin suggesting differentiation toward myofibroblasts; and keloid-like dense collagen. Mast cells are often present (Figs. 5-7 and 5-8) similar to fibrous papule of the nose.

- Fibromas of the anterior hard palate often contain cartilage and branches of the nasopalatine neurovascular bundle (Fig. 5-9).

Differential Diagnosis

- These may be indistinguishable from end-stage mucocele on lower lip or end-stage pyogenic granuloma.
- Sclerotic solitary fibrous tumors are positive for CD34 and may be difficult to differentiate from sclerotic fibroma if areas of more classic vascular proliferation are not present.

Management and Prognosis

- Excision is curative, although continued irritation and trauma may lead to recurrence.

Gingival Masses

Classification is as follows:

- Reactive/inflammatory gingival nodules, solitary or diffuse
- Peripheral (extraosseous) odontogenic cysts and tumors
- Soft tissue tumors (such as nerve sheath or smooth muscle tumors, discussed in Chapter 6)
- Extension of intrabony lesions into the gingiva
- Metastatic tumors to the gingiva

REACTIVE/INFLAMMATORY GINGIVAL NODULES

Clinical Findings

- Young patients in second to fourth decades; nodular masses on the marginal gingiva, often maxillary anterior region; pink, erythematous, dusky purple, or ulcerated; may be painful and, if vascular, will bleed; underlying bone may show "saucerization" of bone (especially with giant cell granuloma) (Fig. 5-10)
- Peripheral giant cell granulomas least common; tend to occur in older adults
- Parulis ("gum-boil") occurs on the attached gingiva; has a punctum and underlying tract that leads to the infected tooth (see later)
- Up to 5% of pregnancies associated with gingival pyogenic granulomas (granuloma gravidarum)

Etiopathogenesis and Histopathologic Features

Pluripotent cells in the gingival tissues when traumatized or irritated (usually by accumulation of dental calculus or bacterial plaque, rough edges of restorations, or presence of implants) differentiate toward endothelial cells, fibroblasts, osteoblasts, or osteoclast-like cells, giving rise to four distinct histologic entities or combinations thereof. Estrogen and progesterone causes overexpression of vascular endothelial growth factor in granuloma gravidarum. See Table 5-1 and Figures 5-11 to 5-19 for histopathologic features.

TABLE 5-1 Reactive Gingival Nodules

Diagnosis	Histopathology
Fibroma (fibrovascular hyperplasia/polyp)	• Nodule of fibrous tissue with scattered vessels and variable edema and inflammation; crevicular epithelium with underlying plasma cells often seen (see Figs. 5-11 and 5-12)
Giant cell fibroma	• In giant cell fibroma, stellate and multinucleated fibroblast–like cells are present (see Fibroma section)
Pyogenic granuloma	• Lobular or nonlobular proliferation of endothelial cells and small, dilated capillaries; often ulcerated and inflamed (see Fig. 5-13, *A*)
	• Endothelial cells show reactive atypia—focal "hobnail" pattern, enlarged nuclei with prominent nucleoli, some mitotic activity (see Fig. 5-13, *B* and *C*)
	• May see fibrosis depending on stage of organization (see Fig. 5-14)
Peripheral ossifying fibroma (fibroma with osseous prosoplasia)	• Cellular proliferation of spindled fibroblast–like cells with ovoid nuclei that have dispersed chromatin, inconspicuous nucleoli; sometimes only subtle osteoid deposits or focal calcifications are present (see Fig. 5-15, *A* and *B*)
	• Osteoid, woven bone, or cementum droplets laid down by spindle cells although osteoblastic rimming sometimes seen (see Figs. 5-15, *C* and *D*, and 5-16)
	• May see clusters of multinucleated giant cells similar to peripheral giant cell granuloma (see Fig. 5-17)
	• Bone morphogenetic protein identified in the spindled fibroblast-like cells
Peripheral giant cell granuloma	• Proliferation of mononuclear and multinucleated giant cells (osteoclast-like or foreign body type) usually in sheets; giant cells contain 10-20 nuclei in a central location; mitoses may be seen in mononuclear cells; fresh hemorrhage and hemosiderin deposits, especially beneath the grenz zone (see Figs. 5-18, 5-19)
	• May see concomitant osseous prosoplasia similar to peripheral ossifying fibroma

- Parulis consists of a mass of edematous granulation tissue with many acute and chronic inflammatory cells and tracts lined by neutrophils (Figs. 5-20 to 5-22); they are often mistaken for mucoceles (which do not occur on the attached gingiva).

Differential Diagnosis

- True infantile hemangiomas show a lobular proliferation of endothelial cells and capillaries that are positive for glucose transporter-1 (GLUT-1) (Fig. 5-23)
- Peripheral odontogenic fibroma produces dentinoid rather than cementum or osteoid and epithelial islands are always present, distinguishing this from peripheral ossifying fibroma (see later).
- Aggressive central (intraosseous) giant cell granulomas may erode through bone; radiographs differentiate them from peripheral (extraosseous) lesions.

Management and Prognosis

- Excision is treatment of choice, although if underlying irritating factors such as dental plaque are not removed, the recurrence rate is up to 15%.
- Granuloma gravidarum may resolve postpartum but may also sclerose and become a gingival fibroma.

DIFFUSE/MULTIFOCAL GINGIVAL HYPERPLASIA

Clinical Findings

- Seen in patients with poor oral hygiene and hormonal changes (e.g., puberty and pregnancy), and in patients on medications such as phenytoin, valproic acid, calcium channel blockers, and cyclosporine
- Diffuse, often slightly nodular enlargement of the gingiva of varying severity (Fig. 5-24, *A* and *B*); leukemic infiltrates may have a similar clinical appearance (see Fig. 5-24, *C*)

Etiopathogenesis and Histopathologic Features

Bacterial plaque induces the proliferation of fibroblasts, and hormones such as progesterone exacerbate this; medications cause a reduction in metalloproteinases, leading to accumulation of matrix.

- Fibrovascular and epithelial proliferation with variable chronic inflammation usually plasmacytic; cytoid bodies sometimes are present if there is prominent spongiosis (Figs. 5-25 and 5-26).
- "Test-tube" rete ridges have been reported in patients on phenytoin and also are seen in patients with conventional non–medication-associated gingival hyperplasia.

Differential Diagnosis

- Presence of an atypical infiltrate should raise suspicion for acute myeloid or monocytic leukemia.
- Presence of pools of eosinophilic material (fibrin that is positive with phosphotungstic acid-hematoxylin) that fills the lamina propria should raise suspicion for ligneous gingivitis/periodontitis, a disorder of plasminogen activator deficiency (Figs. 5-27 and 5-28).

Management and Prognosis

- Excision of hyperplastic tissue, maintenance of good oral hygiene, use of 0.12% chlorhexidine oral rinse, and low-dose doxycycline (20 mg) may reduce recurrence.

Gingival Cyst of the Adult

Clinical Findings

- Usually in the fifth or sixth decade, bluish, slightly fluctuant, dome-shaped nodule on the attached or nonattached gingiva/alveolar mucosa of the mandibular canine-premolar area (80%); some cases bilateral (Fig. 5-29)

Etiopathogenesis and Histopathologic Features

Gingival cyst of the adult forms from cystic degeneration of rests of dental lamina (rests of Serres) in the gingiva (Fig. 5-30).

- Lined by nonkeratinized low cuboidal or squamous epithelium usually two to four cells thick; often see epithelial plaques containing glycogen-rich clear cells sometimes with a swirling architecture (Figs. 5-31 to 5-33)
- Rarely, gingival cyst of the adult may have features of odontogenic keratocyst with parakeratosis and palisading of the basal cells; hyaline Rushton bodies may be present (Figs. 5-34 and 5-35)

Differential Diagnosis

- Sialocyst may occur on nonkeratinized gingiva/alveolar mucosa; often has thicker lining (5 to 10 cells), mucous cells, ciliated cells, or oncocytes and does not show epithelial plaques with clear cells.
- Odontogenic keratocyst that has eroded through bone and manifests in the soft tissues must be ruled out by a radiograph if parakeratin is present in the gingival cyst of the adult.

Management and Prognosis

- Excision is the treatment of choice for the adult form.

Peripheral (Extraosseous) Odontogenic Neoplasms

Although any odontogenic neoplasm may appear on the gingiva (peripheral or extraosseous lesions), the ones seen most frequently include the peripheral odontogenic fibroma (approximately 50% of all cases), peripheral ameloblastoma, and peripheral calcifying cystic odontogenic tumor. Even odontomas may occur in an extraosseous site. Please see Chapter 15 for further discussion of these entities within the bone.

Clinical Findings

- All odontogenic neoplasms manifest as nondescript sessile nodules or masses on the gingiva that may be ulcerated if traumatized, similar to reactive gingival nodules (see earlier).

Etiopathogenesis and Histopathologic Features

Odontogenic neoplasms likely arise from stem cells within odontogenic rests or from pluripotent cells in the basal layer of the surface epithelium.

PERIPHERAL ODONTOGENIC FIBROMA

- Equal distribution exists between maxilla and mandible with 60% to 75% of cases around the incisors/cuspids; adults in the second and fourth decades are affected.
- Cellular proliferation of fibroblast-like spindle cells is present with scattered islands and strands of odontogenic epithelium, some of which may contain clear cells with or without slight palisading of the basal cell nuclei (Fig. 5-36); overlying epithelial proliferation often is present.
- Calcifications manifest in 60% of cases and take the form of osteoid, cementum-like material, or eosinophilic, amorphous dentinoid (resembles acellular osteoid or sometimes cementum) often adjacent to odontogenic epithelium (Fig. 5-37); stroma is collagenized and may be myxoid/mucinous.
- Epithelial islands may be so abundant the term *odontogenic gingival epithelial hamartoma* applies; association with giant cell granuloma is a rare occurrence.
- Significant numbers of granular cells in the stroma raises the diagnosis of peripheral granular cell odontogenic tumor.

Differential Diagnosis

- Peripheral ossifying fibroma has osteoid and cementum and no epithelial islands.
- Fibrous hyperplasia or fibroma may have detached islands of epithelium from tips of rete ridges but lack clear cells.
- Peripheral (extraosseous) dentinogenic ghost cell tumor contains basaloid epithelial cells and ghost cells.

Management and Prognosis

- Excision is the treatment of choice.
- Peripheral odontogenic fibroma may recur in 50% of cases; budding and deep extensions of rete ridges may be associated with higher recurrence.

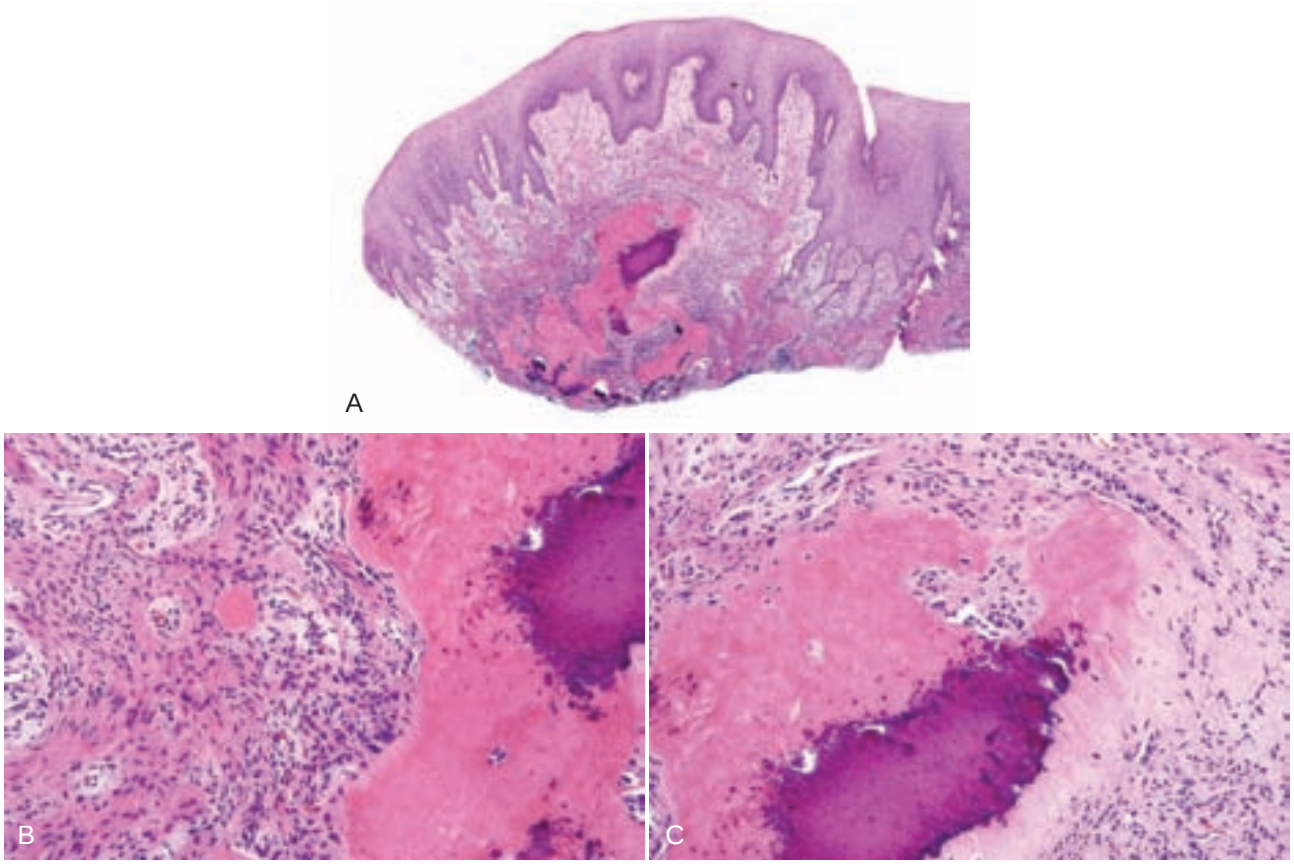

FIGURE 5-37. Peripheral odontogenic fibroma. **A,** Spindle cell proliferation and prominent dentinoid formation. **B,** Spindle cell proliferation and paucicellular dentinoid. **C,** Islands of benign odontogenic epithelium present.

PERIPHERAL AMELOBLASTOMA

- Fifth to sixth decades (older than intraosseous ameloblastoma), usually in the mandible, premolar/molar region
- Proliferation of islands of epithelium with palisading and reverse polarization of the basal cell nuclei (this may be subtle); often seen in continuity with overlying epithelium; center of the islands may show stellate reticulum-like areas or be squamous; no mitotic activity unless traumatized (Figs. 5-38 and 5-39); often CK19 positive
- Stroma collagenized with minimal desmoplasia although peripheral desmoplastic ameloblastoma has been reported

Differential Diagnosis

- Extremely important to rule out (with radiographs) an intraosseous (central) ameloblastoma that has eroded through the cortical bone and lies in the gingiva because peripheral ameloblastomas are not locally aggressive lesions, whereas intraosseous ones are.
- Odontogenic gingival epithelial hamartoma is likely an epithelium-rich variant of the peripheral odontogenic fibroma and shows bland-appearing epithelium without peripheral palisading.
- Extraosseous squamous odontogenic tumors are rare and do not show palisading or reverse polarization of peripheral cells.
- Basaloid squamous cell carcinoma shows significant epithelial atypia and synchronous conventional squamous cell carcinoma.

Management and Prognosis

- Excision is curative; not locally aggressive unlike intraosseous lesions

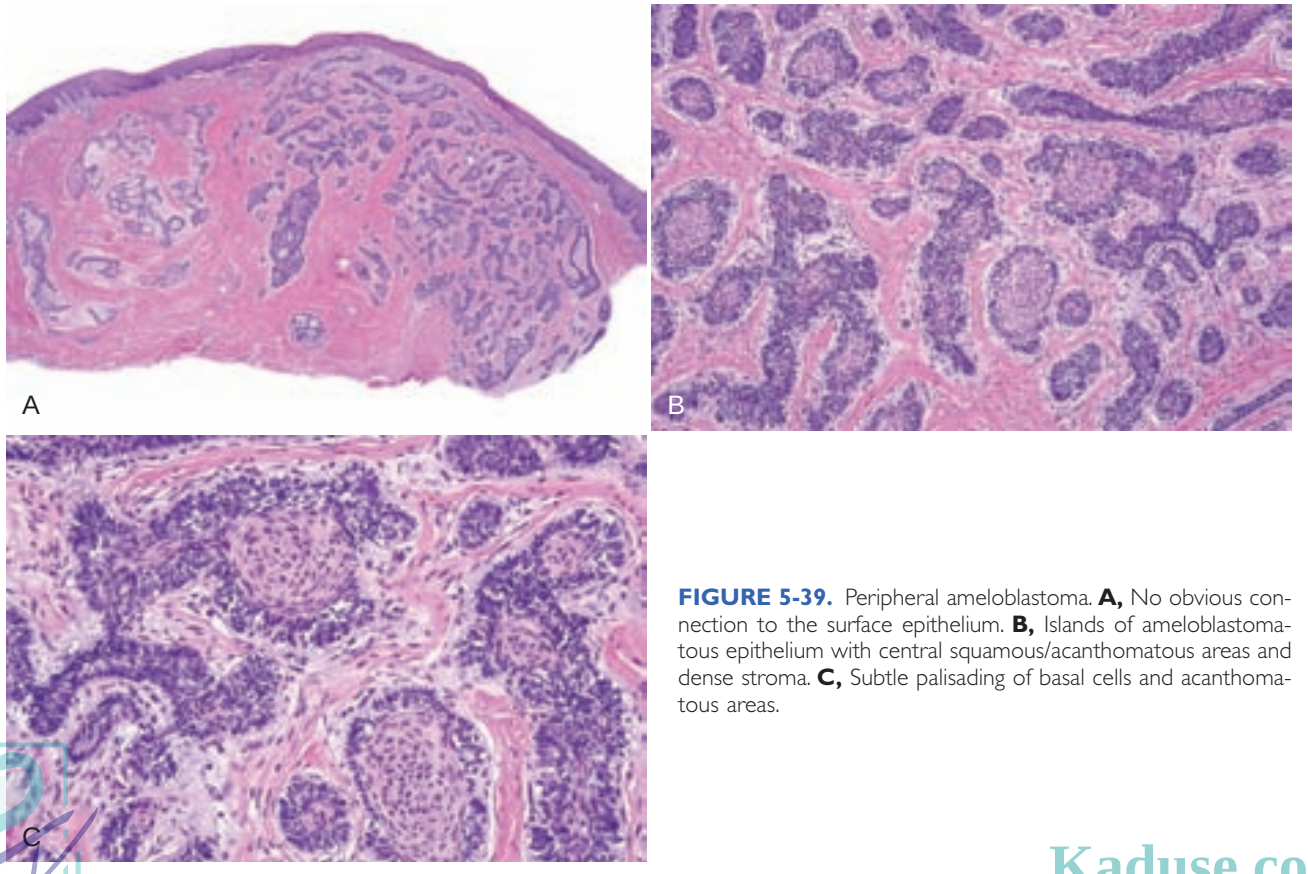

FIGURE 5-39. Peripheral ameloblastoma. **A,** No obvious connection to the surface epithelium. **B,** Islands of ameloblastomatous epithelium with central squamous/acanthomatous areas and dense stroma. **C,** Subtle palisading of basal cells and acanthomatous areas.

PERIPHERAL CALCIFYING CYSTIC ODONTOGENIC TUMOR

- May be either cystic or solid (dentinogenic ghost cell tumor) (see Chapter 15 for a more detailed description).
- Solid variant shows proliferation of basaloid cells that may be ameloblastoma-like, ghost cells, and dentinoid, an amorphous eosinophilic calcified material that resembles acellular woven bone; ghost cells often elicit a foreign body reaction (Figs. 5-40 and 5-41)

Differential Diagnosis

- Peripheral ameloblastoma does not exhibit ghost cell formation or deposits of dentinoid.
- Peripheral odontogenic fibroma contains small islands and cords of epithelium without ghost cell formation, although there may be small deposits of dentinoid.

Management and Prognosis

- Excision is curative.

Metastases to the Gingiva

Two thirds of metastases to the oral cavity occur to the jawbones (80% in the mandible) and one third to the soft tissues, with the gingiva being the most common site, followed by the tongue.

Clinical Findings

- Rapidly enlarging mass on the gingiva in older patients; in 25% to 60% of cases, metastasis may be first indication that a malignancy is present.

Etiopathogenesis and Histopathologic Features

The most common primary sites for such metastases are lung, breast, prostate, kidney, and colon/rectum (Fig. 5-42).

Management and Prognosis

- Generally poor prognosis with low 1-year survival

Denture-Associated Inflammatory Fibrous Hyperplasia (Epulis Fissuratum)

The term *epulis* refers to any mass on gingiva—inflammatory, neoplastic, or cystic—and is nonspecific.

Clinical Findings

- Linear mass of tissue along the flange of a denture in the maxillary or mandibular buccal vestibule/sulcus or floor of mouth, often with a fold in which denture flange rests; denture is loose and poor fitting (Fig. 5-43) (see also Chapter 3)

Etiopathogenesis and Histopathologic Features

- Fibrous tissue proliferates in reaction to trauma from movement of denture on the mucosa
- Fibroepithelial proliferation with a fissured or papillary architecture; variable vascularity and chronic inflammatory infiltrate (usually lymphocytic) that tends to be subepithelial; traumatic neuroma and myositis often present (Figs. 5-44 and 5-45)
- Ulceration and pseudoepitheliomatous hyperplasia not uncommon; presence of spongiotic pustules necessitates a periodic acid–Schiff (PAS) stain with diastase digestion for identification of *Candida*
- Cartilaginous metaplasia sometimes seen

Management and Prognosis

- Excision is curative if the denture is also relined or remade to reduce trauma to tissues.
- Treatment for candidiasis must include decontamination of the denture (see Appendix B).

Lipocytic Lesions

LIPOMA

Clinical Findings

Yellowish soft nodule often on the buccal mucosa and tongue, although any site may be involved; affects adults in the fifth and sixth decades (Fig. 5-46)

Etiopathogenesis and Histopathologic Features

Most so-called lipomas of the buccal mucosa represent herniation of the buccal fat pad (Fig. 5-47). True neoplasms arise from stem cells differentiating toward lipocytes and often show mutation in chromosome 12q.

- Unencapsulated lobules of mature lipocytes are sometimes separated by collagenized fibrous septa; lipocytes have evenly sized lipid vacuoles with no nuclear atypia; bone or cartilage prosoplasia may be present (indistinguishable from osteolipomatous or chondrolipomatous choristomas (Figs. 5-48 and 5-49); the terms *lipofibroma* and *fibrolipoma* are sometimes used, depending on whether fibrous or lipomatous tissue predominates.
- Spindle cell lipomas are true lipocytic neoplasms that are fairly common in the oral cavity, may show mutations in chromosome 13 or 16, and exhibit proliferation of spindle cells with scattered lipocytes, ropy or wiry collagen, mast cells, and dilated vessels (Figs. 5-50 and 5-51, *A* and *B*); cells are CD34 positive (see Fig. 5-51, *C*); the term *myxoid lipomas* is no longer used; pleomorphic lipoma is a variant of spindle cell lipoma with floret-type multinucleated cells.

Differential Diagnosis

- Lipocytes may represent prosoplastic tissue in other lesions such as pleomorphic adenoma and solitary fibrous tumor.
- Degenerative changes in fatty tissue may mimic lesions of atypical lipomatous tumor, and intramuscular lipomas may appear to be pseudoinvasive (Fig. 5-52).
- Atypical lipomatous tumor (well-differentiated liposarcoma of the oral cavity) affects adults in the fifth to seventh decades, occurs on the tongue or buccal mucosa, and contains lipoblasts that exhibit variation in the size of lipid vacuoles, nuclear hyperchromatism, and atypia (that may be subtle) (Fig. 5-53); MDM2 and CDK4 genes are almost always amplified; 10% to 20% recur.

Management and Prognosis

- Excision is curative.

Other Uncommon Tumors

MYOFIBROMA

Solitary myofibroma is more common than myofibromatosis (multifocal disease).

Clinical Findings

- *Myofibromas* are most frequent in first to third decades, often involving the tongue and buccal mucosa; one third are intraosseous (Fig. 5-54).
- *Myofibromatosis* is most frequent in the first and second year of life with 75% of cases being congenital.
- Both present as rubbery masses with or without ulceration.

Etiopathogenesis and Histopathologic Features

Neoplastic proliferation of spindle cells with myofibroblastic and fibroblastic differentiation; histology of both is similar.

- Nonencapsulated, often infiltrative proliferation of short fascicles of spindle cells with abundant pale pink cytoplasm, fusiform nuclei, sometimes grooved, with small nucleoli; perinuclear vacuoles often seen; dilated irregular blood vessels in a "hemangiopericytoma-like" pattern (Fig. 5-55, *A-C*); may see zoning with alternating layers of pale spindle cells and more cellular darker areas containing cells

with less cytoplasm; stroma is slightly chondroid/mucinous (see Fig. 5-55, *D*); may be slightly nodular; degenerative changes or necrosis and myxoid change in up to 60% of cases

- Positive staining for vimentin, smooth muscle actin, muscle-specific actin; negative for S-100 protein, h-caldesmon, and CD34 (see Fig. 5-55, *E*)

Differential Diagnosis

- Fibromatosis (extraabdominal desmoid tumor) is more uniform in appearance, with long sweeping fascicles, is more densely collagenized, and almost always is beta-catenin positive.
- Leiomyoma may be difficult to distinguish from myofibroma; vascularity is not as prominent, although vascular leiomyomas generally have a central vessel; low-grade leiomyosarcoma shows more atypia.
- Nodular fasciitis is infiltrative and typically has "tissue culture" appearance with feathery myofibroblasts and often inflammatory cells and multinucleated giant cells; normal mitoses are often present; spindle cells are positive for smooth muscle actin (Fig. 5-56); some reports suggest that these are true neoplasms, and some cases show abnormalities in chromosomes 3 and 15 and t(2;15).
- Tumors of neural origin are positive for S-100 protein, and cells are smaller with curvilinear nuclei.
- Solitary fibrous tumor has hypercellular and hypocellular areas and is S-100 protein positive; the sclerotic form is densely collagenized.

Management and Prognosis

- Wide surgical excision is treatment of choice; approximately 15% to 30% of myofibromas recur and reports of clinical tumor regression are unusual; one third of myofibromatosis may show regression.

Tumors of Uncertain Histogenesis

ECTOMESENCHYMAL CHONDROMYXOID TUMOR OF THE TONGUE

Clinical Findings

- Firm nodule on the dorsum tongue in adults, usually in the fourth decade

Etiopathogenesis and Histopathologic Features

It is uncertain what tissue these tumors attempt to recapitulate, although some believe that it may represent an unusual myoepithelioma.

- Circumscribed but not encapsulated lobular proliferation of epithelioid, stellate, and spindle cells in a chondromyxoid stroma with tissue clefts (Figs. 5-57 and 5-58, *A, B*); pattern may be pseudocystic, reticular, or solid (see Fig. 5-58, *C-E*); cells have moderate eosinophilic cytoplasm and ovoid-to-round nuclei with dispersed chromatin and inconspicuous nucleoli, although nuclear pseudoinclusions, binucleation, and slight atypia may be seen (see Figs. 5-57, *C,* and 5-58, *F*); ductlike structures are not seen; muscle entrapment is a common finding (see Fig. 5-57, *D*).
- Consistent cytoplasmic positivity for glial fibrillary acidic protein (GFAP), S-100 protein, and vimentin; cytokeratin (AE1/3), CD57, and smooth muscle actin positive in 40% to 75% of cases; generally weak or negative for desmin and epithelial membrane antigen(EMA); negative for myoepithelial markers such as calponin, p63, and smooth muscle myosin heavy chain.

Differential Diagnosis

- Myoepithelioma, soft tissue or otherwise, usually shows positivity for calponin, p63, and smooth muscle myosin heavy chain.
- Pleomorphic adenoma contains ductlike structures and is positive for myoepithelial markers.

Management and Prognosis

- Excision is usually curative; recurrence is possible if margins are involved.

SOLITARY FIBROUS TUMOR

Clinical Findings

- Adults in the sixth decade; most common sites buccal mucosa, maxillary or mandibular sulcus, lip, and tongue (Fig. 5-59)

Etiopathogenesis and Histopathologic Features

Solitary fibrous tumor for the most part replaces the old term *hemangiopericytoma*; differentiation is toward a spindle cell that is CD34 positive.

- Circumscribed, sometimes encapsulated mass of spindle and ovoid cells with two patterns: classic pattern—small and large stag-horn vessels with proliferation of spindle cells in either hyalinized or myxoid stroma, characteristically with hypercellular and hypocellular areas (Fig. 5-60); sclerotic pattern—dense, sclerotic, and hyalinized collagen with only subtle and focal classic features; cells have indistinct cell borders and benign nuclei with small, inconspicuous nuclei (Fig. 5-61, *A-D*); CD34 and sometimes Bcl-2 positive (see Fig. 5-61, *E*); periductal hyalinization seen in salivary gland involvement (Fig. 5-62, *A, B*)
- Multinucleated tumor giant cells, mature lipocytes, and lymphocytes are present (see Fig. 5-62, *C*); presence of lipoblasts should prompt careful search for evidence of malignancy.
- Dedifferentiation leads to anaplasia and loss of CD34 positivity

Differential Diagnosis

- Nerve sheath tumors have curvilinear nuclei and are S-100 positive although some ancient schwannomas may show similar dense and delicate collagenization.
- Vascular neoplasms show a proliferation of spindle or epithelioid endothelial cells that form vessels with cytoplasmic positivity for CD31; intracellular lumina are not present in solitary fibrous tumor.
- Sclerotic fibroma and desmoid tumor are uniformly sclerotic and hyalinized with little areas of hypercellularity.
- Myopericytoma has CD34-positive endothelial cells, whereas the perivascular spindle cell proliferation is positive for smooth muscle actin.

Management and Prognosis

- Excision is curative and recurrence is rare.

ORAL FOCAL MUCINOSIS

Clinical Findings

- Soft, gelatinous nodule of gingiva in adults (fifth decade) (Fig. 5-63)

Etiopathogenesis and Histopathologic Features

Oral focal mucinosis may be a response to inflammation.

- Nonencapsulated pool(s) of mucinous or myxoid alcianophilic ground substance with scattered S-100–negative spindle and stellate cells and short bands of collagen; reticulin fibers may not be evident (Figs. 5-64 and 5-65).
- Fibrous hyperplasias of the gingiva often show myxoid change; it may be that accumulation of such ground substance results in focal mucinosis.

Differential Diagnosis

- Soft tissue angiomyxoma, a rare mesenchymal neoplasm in the mouth, is better demarcated and homogeneous with delicate collagen fibers and many dilated vessels; reticulin fibers are present and may be difficult to distinguish from focal mucinosis (Fig. 5-66).
- Mucoceles have pools of mucin surrounded by granulation tissue containing muciphages.
- Myxoid neurofibroma and neurothekeoma (usually multilobular) stain for neural markers.
- Superficial angiomyxoma is a rare myxoid tumor that contains numerous blood vessels with occasional CD34-positive spindle cells, and may behave aggressively.

Management and Prognosis

- Excision is curative.

6 Vascular, Neural, and Muscle Tumors

CHAPTER CONTENTS

Vascular Lesions

PYOGENIC GRANULOMA

Clinical Findings

- Purple-to-red nodule or papule, sessile or pedunculated; common on the gingiva (75% of cases [see Chapter 5]), upper lip, and buccal mucosa; there may be a history of bleeding (Fig. 6-1, *A* and *B*).
- Patients on cyclosporine after stem cell transplantation develop pyogenic granuloma–like lesions on the buccal mucosa or tongue rather than the gingiva (see Fig. 6-1, *C*).

Etiopathogenesis and Histopathologic Features

Pyogenic granuloma represents a reactive proliferation of endothelial cells and blood vessels.

- Proliferation of endothelial cells and capillaries (often dilated)—sometimes in a lobular pattern, often with overlying ulceration—and acute and chronic inflammation are seen; mitoses are not uncommon (Figs. 6-2 and 6-3).
- Some lesions may show significant reactive atypia with hyperchromatic and pleomorphic nuclei (Fig. 6-4).
- Fibrous ingress signals organization, and lesions may convert to fibromas—especially gingival lesions (Fig. 6-5).

Differential Diagnosis

- Edematous polypoid masses seen in patients after stem cell transplantation on cyclosporine are better diagnosed as reactive fibrovascular polyps.

Management and Prognosis

- Excision is treatment of choice with recurrence in less than 5% of cases.

VARIX (VENOUS LAKE) AND VENOUS MALFORMATION (VENOUS ANOMALY)

Clinical Findings

- Usually bluish blebs are less than 1 cm and found on the lips, tongue, or buccal mucosa, which may bleed; seen in middle-aged and older adults (Fig. 6-6, *A-C*).
- Bilateral ingual varices of the ventral tongue are common in older adults (see Fig. 6-6, *D*).
- Venous malformations are larger, often several centimeters in size, and usually are located on the tongue or lips (see Fig. 6-6, *E*).

Etiopathogenesis and Histopathologic Features

Loss of elasticity of the muscle around venules (likely superficial postcapillary venules) leads to dilatation of the lumen.

- *Varix:* dilated, tortuous, thin-walled vessels with a thin muscular coat; valve leaflets may be present (Figs. 6-7 and 6-8); thrombi in various stages of organization often noted with high cellularity or hyalinization; Masson tumor (intravascular papillary endothelial hyperplasia) sometimes seen (Figs. 6-9 to 6-11)
- *Venous malformation:* proliferation of venules of varying sizes, sometimes intramuscular in location without proliferation of endothelial cells (Figs. 6-12 and 6-13)

Differential Diagnosis

- Arteriovenous malformations show the presence of both arterioles and arteries and veins and venules; these lesions have high flow, and biopsy may lead to a severe bleeding episode.
- Hereditary hemorrhagic telangiectasia shows the presence of numerous small capillaries and venules in the lamina propria.

Management and Prognosis

- Excision, laser ablation, and sclerotherapy with ethanolamine oleate are useful treatments.

CALIBER-PERSISTENT LABIAL ARTERY

Clinical Findings

- Bluish, sometimes nodular, often vermiform, pulsatile lesion of the lower lip in adults; often mistaken for mucocele

Etiopathogenesis and Histopathologic Features

Lesions are caused by branches of the labial artery that fail to reduce their caliber, even in the superficial tissues.

- Normal artery with elastic lamina lies within the lamina propria with an artery diameter-to-depth ratio of less than 1.6 (Fig. 6-14).

Management and Prognosis

- Trauma leads to pulsatile bleeding, and biopsy is diagnostic.

KAPOSI SARCOMA

Kaposi sarcoma is currently classified as a neoplasm of intermediate (nonmetastasizing) potential because of ambiguity regarding its biologic nature.

Clinical Findings

- There are four clinical presentations: (1) classic type involves the skin of lower legs in older men; (2) African endemic type is disseminated and involves viscera; (3) iatrogenic type is associated with immunosuppression (especially renal and lung transplantation); and (4) epidemic type is found in patients with HIV/AIDS and involves multiple sites, especially the skin and the mouth (this coexists with the endemic form in Africa).
- Dusky red or purple macule (early lesion), plaque, or mass (late lesion) is usually on the maxillary gingiva, palate, or tongue (Fig. 6-15); oral involvement is seen in only 2% to 5% of nonepidemic cases and in 60% to 70% of patients with HIV/AIDS.
- Worsening of Kaposi sarcoma is one of the features of patients on highly active antiretroviral therapy who develop immune reconstitution inflammatory syndrome.

Etiopathogenesis and Histopathologic Features

This tumor is associated with activity of Kaposi sarcoma–associated herpesvirus (human herpesvirus-8); transmission may be through saliva rather than through blood or semen. Activation of viral lytic and latency genes leads to tumorigenesis, with initial tumor cells being polyclonal and more advanced tumors being monoclonal and immortalized.

- Cellular proliferation of spindle cells in small whorls or fascicles with abundant extravascular erythrocytes, hemosiderin and globular eosinophilic deposits, and some intracytoplasmic granules; mitotic activity may be noted (Figs. 6-16 and 6-17).
- Studies for endothelial markers such as CD31, CD34, FLI-1, and Kaposi sarcoma–associated herpesvirus (especially LANA-1) are positive; studies for D2-40 may also be positive.

Differential Diagnosis

- Spindle cell angiosarcoma and solitary fibrous tumor are negative for Kaposi sarcoma–associated herpesvirus.
- Monophasic synovial sarcoma is not a vascular tumor and is CD31 negative with ductlike structures that are cytokeratin positive.

Management and Prognosis

- Patients newly diagnosed with HIV/AIDS require highly active antiretroviral therapy. Oral lesions are successfully treated with excision, laser ablation, intralesional vinblastine therapy, and radiation.
- Systemic therapy includes pegylated liposomal doxorubicin or daunorubicin.
- Reduction in immunosuppressive therapy in post-transplantation patients often leads to regression of tumors.

LYMPHATIC MALFORMATION (LYMPHANGIOMA CIRCUMSCRIPTUM)

Unlike cystic hygromas, lymphatic malformations of the oral cavity are usually superficially located and smaller.

Clinical Findings

- Clusters of translucent vesicular structures, usually on the tongue (50% of cases) in young adults (Fig. 6-18); typically described as "frog spawn"

Etiopathogenesis and Histopathologic Features

This developmental malformation of lymphatic structures exhibits the absence of vascular endothelial growth factor C, which regulates lymphatic development. It is consistent with a process of lymphatic dilatation rather than neoplasia.

- Vascular spaces lined by a single layer of endothelial cells (D2-40 positive) with valvelike structures, filled with pale, wispy, or denser eosinophilic material; typically abut the epithelium and may insinuate into the muscle (Figs. 6-19 and 6-20)

Differential Diagnosis

- Venous malformations show a thin muscular coat and usually do not abut the epithelium.

Management and Prognosis

- Excision is curative for small lesions, and debulking or embolization is treatment for large lesions.

Neural Tumors

Neural tumors are the most common benign spindle cell lesions in the oral cavity.

Clinical Findings

- Solitary nodule is on the tongue, lips (especially upper labial mucosa), and palate (Fig. 6-21).
- Traumatic neuromas are often painful and seen at sites of previous surgery or frequent trauma (e.g., lip, tongue, and mental nerve area in the edentulous mandible, the last from denture trauma).
- Multiple nodules on the lips and tongue strongly suggest mucosal neuromas of multiple endocrine neoplasia (MEN) type 2B; these are associated with thyroid medullary carcinoma and pheochromocytoma (see later).
- Neurofibroma, either solitary or multiple, may be associated with neurofibromatosis type 1.

TRAUMATIC NEUROMA

Etiopathogenesis and Histopathologic Features

Traumatic partial or total severance of nerve fibers leads to a tangle of nerves and scarring.

- Numerous nerve fibers of varying sizes with some showing mucinous change; fibrosis and scarring occurs between fibers (Figs. 6-22 and 6-23, *A* and *B*).
- Spindle cells are S-100 protein positive and neurofilament protein highlights axons (see Fig. 6-23, *C*)

Differential Diagnosis

- Mucosal neuromas of MEN show hyperplasia of nerve fibers with thickened perineurium but an absence of fibrosis and scarring.

Management and Prognosis

- Excision is curative.

NEUROFIBROMA

Etiopathogenesis and Histopathologic Features

Neurofibromas are usually solitary and sporadic; some (especially plexiform type) are seen in patients with neurofibromatosis type A (from inactivating NF-1 gene mutation on chromosome 17q). It is associated with other signs of neurofibromatosis such as café au lait macules, Lisch nodules, and multiple skin neurofibromas.

- Nonencapsulated, discrete or diffuse proliferation of perineurial cells, fibroblasts, and Schwann cells in a delicately collagenized stroma with variably myxoid or mucinous background; cells with curvilinear, comma-shaped, or ovoid nuclei with inconspicuous nucleoli and indistinct cytoplasmic borders; scattered S-100–positive Schwann cells and occasional neurites identified; mast cells often present (Figs. 6-24 and 6-25)

Differential Diagnosis

- Neurothekeoma has lobulated appearance, and cells are epithelioid.
- Soft tissue myxoma is S-100 negative.
- Solitary circumscribed neuroma has many neurites, slight nuclear palisading, and tissue clefts.
- Mucosal neuroma consists of nodules of tortuous and enlarged nerve fibers usually on the lips and tongue (Fig. 6-26). It is associated with MEN type 2B together with medullary thyroid carcinoma, pheochromocytomas (often bilateral), eyelid neuromas causing lid eversion, intestinal ganglioneuromatosis, and marfanoid phenotype; autosomal dominant condition is caused by a mutation in the RET gene on chromosome 10.

Management and Prognosis

- Excision is curative.
- Plexiform neurofibroma in patients with neurofibromatosis may undergo malignant transformation, and p53, p16, and p27 may be involved in tumor progression.

SCHWANNOMA

Etiopathogenesis and Histopathologic Features

Schwannoma represents a neoplastic proliferation of Schwann cells and axons, developing eccentrically from the surface of nerves; it is sometimes seen in neurofibromatosis type 2.

- Encapsulated proliferation of spindled Schwann cells in delicately collagenized stroma with two patterns: *Antoni type A pattern* exhibits Verocay bodies composed of palisaded nuclei and intervening eosinophilic accumulation of basement membrane–like material (Figs. 6-27 and 6-28, *A* and *B*); *Antoni type B pattern* has a more nondescript appearance with myxoid background (see Fig. 6-28, *C*): tumors are consistently S-100 positive and sometimes neurofilament protein (NFP) positive; capsule of perineurium is epithelial membrane antigen (EMA) positive.
- Ancient schwannomas show degenerative changes such as hemorrhage, hyalinization, cystic degeneration of stroma, atypical spindle cells with large nuclei, and variable inflammation (Fig. 6-29).

Differential Diagnosis

- Neurofibromas are usually not encapsulated and do not contain Verocay bodies.
- Solitary circumscribed neuroma show some palisading of nuclei but contain many neurites and tissue clefts.
- Solitary fibrous tumor contains staghorn vessels, and cells are CD34 positive.
- Some leiomyomas demonstrate Verocay body–like formations but are S-100 negative.

SOLITARY CIRCUMSCRIBED NEUROMA (PALISADED ENCAPSULATED NEUROMA)

Etiopathogenesis and Histopathologic Features

Solitary circumscribed neuroma is likely a neoplastic proliferation of Schwann cells and neurites, possibly within a nerve.

- Approximately 75% of lesions occur on the palate or gingiva; the labial mucosa is the second most common site, and lesions occur in adults in their fifth decade.
- Circumscribed and sometimes partially encapsulated, unilobular, multilobular, or plexiform proliferation of Schwann cells, neurites, and fibroblasts occur in a delicately collagenized stroma; palisading of nuclei is characteristic; nuclei are ovoid or fusiform with dispersed chromatin and inconspicuous nucleoli; tissue clefts are a reliable feature (Figs. 6-30, *A-C*, 6-31 and 6-32); some lesions are predominantly myxoid.
- Spindle cells are S-100 positive; neurites are neurofilament protein positive (see Fig. 6-30, *D*), usually glial fibrillary acidic protein (GFAP) negative, and EMA, glucose transporter type 1 (GLUT-1), and claudin-1 positive cells around the lobules; epithelioid and vascular variants have been reported.

Management and Prognosis

- Excision is treatment of choice; recurrence is rare.

GRANULAR CELL TUMOR

Clinical Findings

- Seen in adults; firm mass; may be slightly yellowish beneath intact epithelium; occurs more commonly on the tongue and lips; other sites include buccal mucosa and floor of the mouth (Fig. 6-33).

Etiopathogenesis and Histopathologic Features

Granular cell tumor is believed to be of neural origin and stains for neural markers; cytoplasm is granular because of lysosomes.

- Nonencapsulated proliferation of cells with granular cytoplasm that sometimes contain eosinophilic globules; cells may be in sheets or nodules; cells often insinuate between skeletal muscle fibers; nuclei have dispersed chromatin and inconspicuous nucleoli without atypia or mitotic activity; overlying epithelium may exhibit pseudoepitheliomatous hyperplasia or be atrophic (Figs. 6-34 and 6-35, *A-C*).
- Cytoplasmic staining for S-100 protein, CD68, and PGP 9.5 (see Fig. 6-35, *D* and *E*).
- Plexiform granular cell tumor is a variant; it forms fascicles and nodules that encase nerves, vessels, and skin adnexa.

Differential Diagnosis

- Congenital granular cell tumor occurs on the gingiva of neonates; tumor has arborizing small vessels, and it is S-100 negative.
- Primitive polypoid nonneural granular cell tumor often has a collarette of epithelial cells at the base, is S-100 negative, is NK1-C3 and CD68 positive, and may show nuclear atypia and mitotic activity.
- Granular cells may be seen focally in other tumors such as benign histiocytoma and leiomyoma and may indicate degenerative change.
- Pseudoepitheliomatous hyperplasia does not show significant atypia of squamous cell carcinoma.

Management and Prognosis

- Excision is curative; malignant forms are rare.

SUBGEMMAL NEUROGENOUS PLAQUE (SUBEPITHELIAL NERVE PLEXUS)

Clinical Findings

- Mucosa-colored papule or plaque is found on the posterior lateral tongue; sometimes it is associated with burning and usually occurs in adults in the sixth decade.

Etiopathogenesis and Histopathologic Features

Subgemmal neurogenous plaque is thought by some to represent a reactive proliferation of Schwann cells, axons, perineurial cells, and endoneurial fibroblasts, possibly from trophic stimulation arising from gustatory nerve fibers.

- Delicate nerve plexus is composed of spindle cells with curvilinear nuclei; ganglion cells sometimes are seen in the deeper areas; overlying epithelium

contain taste buds typical for this site (Fig. 6-36, *A-C*); cytoplasm is positive for S-100 protein, neurofilament protein, and PGP9.5 (see Fig. 6-36, *D* and *E*).

Differential Diagnosis

- Diffuse neurofibroma and traumatic neuroma may look similar, but this combination of nerve sheath cells and axons without scarring to differentiate them.
- It is not clear whether some subgemmal plaques represent normal neural plexi beneath the foliate papillae of the lateral tongue, because similar structures are noted beneath most taste buds.

Management and Prognosis

- Excision is curative.

Muscle Tumors

LEIOMYOMA AND ANGIOLEIOMYOMA (VASCULAR LEIOMYOMA)

Clinical Findings

Painless nodule usually is present in the upper lip (50% of cases) of adults; the palate is the second most common site (25% of cases) (Fig. 6-37).

Etiopathogenesis and Histopathologic Features

This benign neoplasm shows differentiation toward smooth muscle.

- Unencapsulated, discrete proliferation of smooth muscle cells appear in sweeping fascicles; in angioleiomyoma or vascular leiomyoma, fascicles may show a whorled configuration around a central endothelium-lined space; smooth muscle cells have pale, eosinophilic, vacuolated cytoplasm, and elongated, sometimes cigar-shaped, nuclei (Figs. 6-38, *A* and *B*, 6-39, and 6-40, *A-C*).
- Cytoplasm is positive for smooth muscle actin, muscle-specific actin, and desmin (see Figs. 6-38, *C* and 6-40, *D*); there is no evidence of cytologic atypia.
- Granular cell and epithelioid variants have been reported.

Differential Diagnosis

- Myofibroma has a chondroid-appearing stroma, may have zoning phenomenon, and occurs in younger patients.
- Nodular fasciitis shows a proliferation of spindle cells with "tissue culture" appearance, abundant myxoid or mucinous stroma, often multinucleated giant cells, and a mixed inflammatory infiltrate; borders are not sharply demarcated, and there is cytoplasmic positivity for smooth muscle actin and muscle-specific actin.
- Leiomyosarcoma and fibrosarcoma exhibit cytologic atypia, and high-grade lesions show pleomorphism and mitotic activity.
- Sarcomatoid carcinoma exhibits significant cytologic atypia and positivity for pancytokeratin (see Chapter 11).

Management and Prognosis

- Excision is curative.

ADULT RHABDOMYOMA

Unlike the more common cardiac rhabdomyoma, extracardiac rhabdomyomas are not associated with tuberous sclerosis or other phakomatosis. More than 90% of adult extracardiac rhabdomyomas occur in the head and neck, especially in the larynx and pharynx. Adult (more common) and fetal types (in children) are recognized.

Clinical Findings

- Adults in sixth to seventh decade with 3 to 1 male predilection.
- Mucosal, nontender mass in the tongue or larynx or pharynx causing obstructive symptoms; 3% to 5% are multifocal.

Etiopathogenesis and Histopathologic Features

This benign neoplasm shows differentiation toward skeletal muscle fibers.

- Encapsulated proliferation of large, polyhedral cells with brightly eosinophilic cytoplasm that are often vacuolated, but not to the extent of cardiac rhabdomyomas (Fig. 6-41, *A-C*); small nuclei with indistinct nucleoli; muscle striations and rodlike inclusions can be seen with phosphotungstic acid and trichrome stains (see Fig. 6-41, *D*); cells contain glycogen that is positive with periodic acid–Schiff stain and diastase labile; there is scant stroma.
- Cells are positive for muscle-specific actin, desmin, and myoglobin.
- Fetal type features spindle cells with myotubules and rhabdomyoblast-like cells in a myxoid stroma.

Management and Prognosis

- Excision is treatment of choice; recurrence rate is up to 40% mainly because of incomplete excision.

EMBRYONAL RHABDOMYOSARCOMA

Rhabdomyosarcoma is the most common soft tissue sarcoma in children (accounting for 3% of childhood malignancies); the embryonal rhabdomyosarcoma is the most common type. Alveolar rhabdomyosarcoma tends to occur on the extremities, and it usually shows translocation t(2;13)(q35;14) leading to PAX3-FOX01 fusion; sclerosing and spindle cell are other subtypes.

Clinical Findings

- Usually occurs in the first decade, often younger than age 5; approximately 50% occur in the head and neck with the genitourinary tract being next most common site
- Rapidly growing mass in the cheek, buccal mucosa, or tongue

Etiopathogensis and Histopathologic Features

Embryonal rhabdomyosarcoma is a malignant neoplasm that recapitulates embryonic striated muscle and includes botryoid, spindle cell, and anaplastic subtypes; deletions on short arm of chromosome 11 are often seen.

- *Embryonal type:* stellate-shaped, small ovoid, and spindle cells with cellular compact areas and less cellular myxoid areas; differentiation leads to cells with eccentric nuclei and more abundant eosinophilic cytoplasm and characteristic "strap" cells (Fig. 6-42)
- *Botryoid type:* multinodular growth pattern with similar cells but with a hypercellular area (cambium layer) just beneath the epithelium
- *Anaplastic type:* anaplastic cells with atypical, hyperchromatic, and pleomorphic nuclei often with bizarre mitotic figures
- *Spindle cell type:* spindle cells with rhabdomyoblastic or smooth muscle features in a storiform or fasciculated pattern; controversial as to whether this belongs within this category
- Less differentiated cells vimentin positive; more differentiated cells desmin, muscle-specific actin, myoglobin, and Myo-D1 (nuclear staining) positive

Differential Diagnosis

- Fetal rhabdomyomas do not show nuclear atypia.
- Lymphoma, neuroblastoma, primitive neuroectodermal tumor, and other small blue cell tumors must be ruled out with immunohistochemical studies.

Management and Prognosis

- Surgical excision is treatment of choice with adjuvant radiotherapy as needed; new protocols that include chemotherapy have improved 5-year survival to 70%.
- Prognosis is dependent on stage, histologic type (embryonal tumors have better prognosis than alveolar or anaplastic types), age (patients younger than 10 years old fare better), and site (orbital and head and neck nonparameningeal tumors have better outcome).

7 Ulcerative and Inflammatory Conditions

CHAPTER CONTENTS

Ulcerative Conditions

RECURRENT APHTHOUS ULCERS AND TRAUMATIC ULCERS

Most cases of recurrent aphthae are idiopathic; however, aphthous-like lesions are seen in Behçet disease, Crohn disease (often linear in the sulcus), hematinic deficiencies, some hypersensitivity reactions (to food, sodium lauryl sulfate found in toothpaste), cyclic neutropenia, and HIV infection. Complex aphthosis is often used to describe lesions associated with syndromes affecting the skin. Ulcers in children may be part of periodic fever, aphthosis, pharyngitis, and adenopathy (PFAPA) syndrome. Trauma and stress bring on episodes in susceptible individuals. Minor aphthous ulcers do not tend to be biopsied because of the typical history and presentation, whereas major ulcers are biopsied to rule out vesiculobullous disease. Chemotherapy-induced ulcerations are much larger, resolve predictably over 1 to 2 weeks, and are not aphthous ulcers.

Traumatic Ulcers

Traumatic ulcers are caused by trauma—usually on buccal mucosa, tongue, and lower lip (also on sites of morsicatio mucosae oris)—and are indistinguishable histologically from recurrent aphthous ulcers. They also occur secondarily on lesions that protrude (e.g., fibromas and gingival nodules).

Clinical Findings

- Recurrent aphthous ulcers begin in the second and third decades of life and diminish in severity with age; ulcers are episodic or continuous and only on the nonkeratinized mucosa, although tongue dorsum may be involved in hematinic deficiency; a yellow fibrin membrane with surrounding erythema is present (Fig. 7-1, *A-C*).
- Minor ulcers are the most common, are smaller than 1 cm in size, and last 1 to 2 weeks; major ulcers are the least common, are larger than 1 cm in size, last for weeks or months, and often are associated with scarring—this form is often seen in HIV/AIDS. Herpetiform ulcers are uncommon and number more than 10 minor ulcers at each episode; severe aphthous ulcers present as continuous ulcerations.
- Traumatic ulcers can occur whenever there is history of trauma, particularly if the area is protuberant (see Fig. 7-1, *D* and *E*).

Etiopathogenesis and Histopathologic Features

Most cases of recurrent aphthae have a strong family history of recurrent aphthae, and some HLA-A haplotypes have been identified. TNF-α plays an important role in etiopathogenesis.

- Fibrin membrane with enmeshed neutrophils and underlying granulation tissue with acute and chronic inflammatory cells confined to the lamina propria; adjacent epithelium exhibits spongiotic pustules and reactive atypia (such as multinucleated epithelial cells and basal cell hyperplasia) (Fig. 7-2); traumatic ulcers often show adjacent hyperparakeratosis and surface bacterial colonies.
- Early or healing lesions show subepithelial fibrin deposition, spongiotic pustules, reactive epithelial atypia with multinucleated epithelial cells, and often intraepithelial hemorrhage (Fig. 7-3).
- Spread of inflammation to underlying muscle may lead to presence of eosinophils and histiocyte-like mononuclear cells (Fig. 7-4) (see Traumatic Ulcerative Granulomas later in this chapter.)

Differential Diagnosis

- Evaluate for herpes simplex virus in the adjacent epithelium, and cytomegalovirus and fungi in the lamina propria in immunocompromised patients.
- Neutropenic ulcers have scarce neutrophils (Fig. 7-5).
- Medication-induced oral ulcers are not strictly aphthae and are particularly dramatic in patients on mammalian target of rapamycin (mTOR) inhibitors.
- Coagulation of the epithelium suggests concomitant contact with a caustic agent.

Management and Prognosis

- Topical or systemic steroid therapy or other immunosuppressive agents (see Appendix A) and topical analgesia are indicated.
- For systemic conditions presenting with aphthous-like ulcers, careful history-taking and work-up are important.
- Adenotonsillectomy may be effective in some patients with PFAPA syndrome.

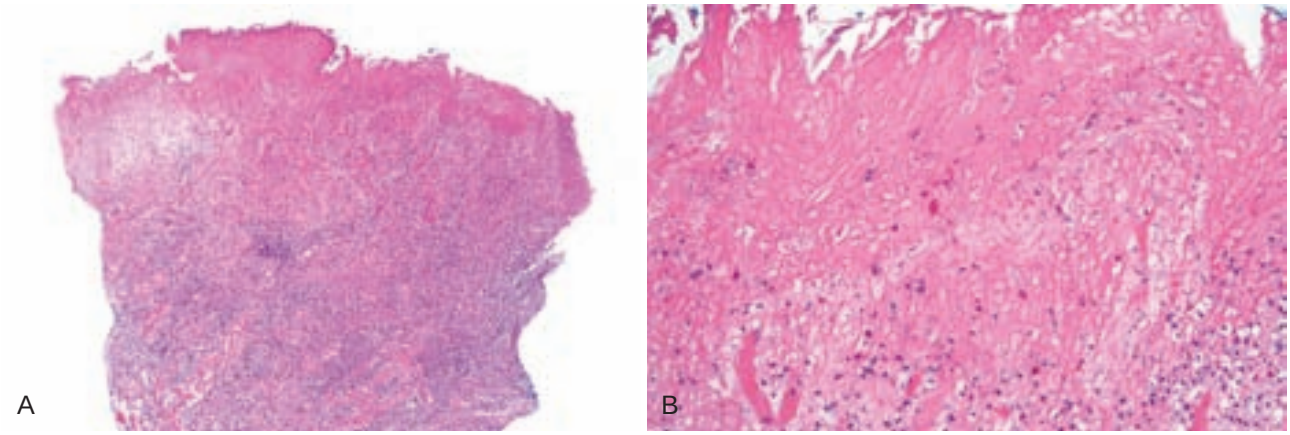

FIGURE 7-5. A, Neutropenic ulcer. **B,** Paucity of neutrophils within fibrin meshwork.

TRAUMATIC ULCERATIVE GRANULOMA WITH STROMAL EOSINOPHILS, EOSINOPHILIC ULCER OF TONGUE

Clinical Findings

- Adult form is sharp, punched-out ulcer often with a white, keratotic rim, commonly on the lateral tongue, present for weeks, with or without pain, and raising suspicion for malignancy; any site with underlying muscle may be involved (Fig. 7-6, *A*); synchronous bilateral lesions or metachronous lesions may occur (see Fig. 7-6, *B*).
- Riga-Fede disease is an ulcer on tongue or lower lip in first year of life when newly erupted incisors traumatize mucosa (see Fig. 7-6, *C*).

Etiopathogenesis and Histopathologic Features

Ulcerative granuloma is secondary to deeply penetrating inflammation involving the underlying skeletal muscle and is most often associated with trauma, but it may also be seen in chronically traumatized ulcerative conditions, such as aphthous ulcers or other chronic inflammatory conditions; it bears resemblance to proliferative myositis.

- Ulcer with acute and chronic inflammation that penetrates into the muscle with separation and degeneration of muscle fibers (sometimes with "checkerboard" pattern), proliferation of histiocyte-like mononuclear cells, and many eosinophils (Figs. 7-7 and 7-8).
- Mononuclear cells are CD68 and Factor XIIIa positive (see Fig. 7-8, *D*).
- Exuberant granulation tissue may form a polypoid mass (pyogenic granuloma–like).

Differential Diagnosis

- Diffuse large B-cell lymphomas show sheets of histiocyte-like cells that are CD20+; it is unclear if previously reported cases of atypical histiocytic granuloma may represent such lymphomas.
- Sheets of CD30+ cells raise the possibility of lymphoma, although this must be evaluated with clinical

findings; even monoclonality may not indicate neoplasia.

- Epstein-Barr virus–associated mucocutaneous ulcers contain many CD30+ and EBV-encoded RNA (EBER) positive B cells, T cells, atypical Hodgkin-like cells, and Reed-Sternberg–like cells, with some cases showing B and T cell clonality; some cases regress, whereas others relapse and remit.

Management and Prognosis

- Lesions may heal after biopsy; otherwise, topical steroids, excision, or intralesional steroid injections are indicated (see Appendix A).
- Recurrence is common, especially if patient has flabby or enlarged tongue (e.g., older patients who wear lower full dentures or who have lost teeth in the posterior mandible).

Nonspecific Inflammatory Conditions

NONSPECIFIC IRRITANT CONTACT STOMATITIS

Clinical Findings

- White, necrotic plaque with or without ulceration with an erythematous background and a history of exposure to contactant

Etiopathogenesis and Histopathologic Features

Irritation by contactant is stronger than that seen with alcoholic mouth rinses and leads to inflammatory changes. Stronger irritants (e.g., aspirin) lead to necrosis and ulceration.

- Epithelial hyperplasia with marked spongiosis and leukocytic (especially neutrophilic) exocytosis; ulceration may be present (Figs. 7-9 to 7-11); some lesions show coagulation of the superficial keratinocytes with reactive keratinocytic atypia, and karyorrhexis (see Fig. 7-11) (see also Smokeless Tobacco Lesion in Chapter 10).

Differential Diagnosis

- Presence of a large number of eosinophils in the epithelium suggests hypersensitivity reaction.
- Contact stomatitis caused by restorations or cinnamic aldehyde–containing products result in lichenoid reactions.

Management and Prognosis

- Abstain from using contactant.
- Topical steroid therapy resolves lesions (see Appendix A).

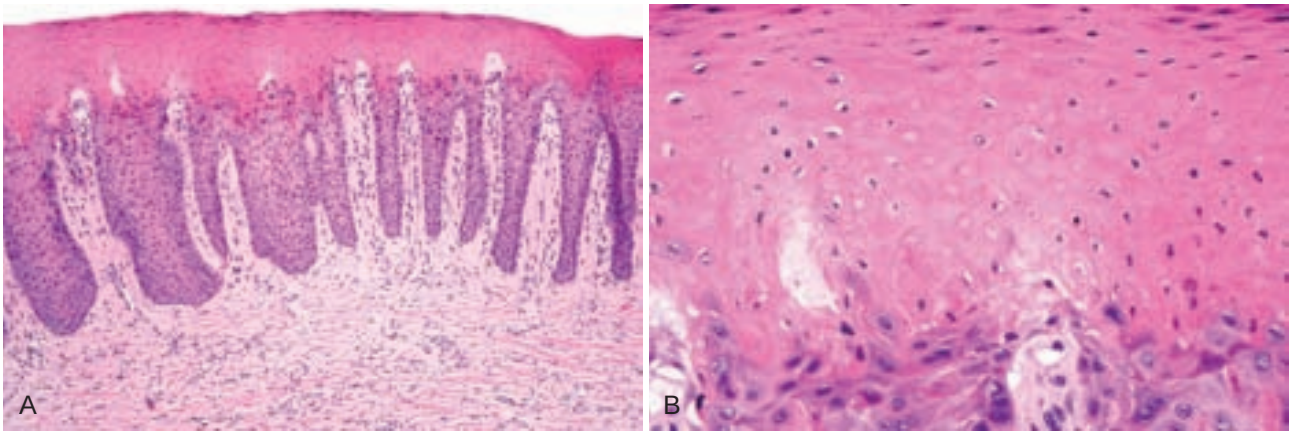

FIGURE 7-11. Irritant contact stomatitis. **A,** Hyperparakeratosis and coagulation of superficial keratinocytes. **B,** Coagulated superficial keratinocytes with reactive epithelial atypia and karyorrhexis.

FRICTIONAL BLISTERS

Clinical Findings

- Blisters occur at sites of trauma, particularly on the nonkeratinized mandibular or maxillary sulci traumatized by denture flanges.

Etiopathogenesis and Histopathologic Features

Traumatic shear forces separate the epithelium from the connective tissue.

- Benign epithelial hyperplasia with intraepithelial or subepithelial blistering and accumulation of serum or fibrin; variable inflammation and vascular ectasia (Figs. 7-12 and 7-13)
- Bright eosinophilic pools of plasma ("plasma pooling"), further evidence of surface injury (Fig. 7-14)

Differential Diagnosis

- Lymphatic malformations or lymphangioma circumscriptum consists of endothelium-lined spaces that abut the epithelium.
- Mucous membrane pemphigoid does not usually exhibit marked epithelial hyperplasia and accumulation of fluid or fibrin.
- Superficial mucoceles exhibit subepithelial collections of mucin and muciphages.

Management and Prognosis

- Lesions resolve if source of trauma is removed.

CHRONIC GINGIVITIS

Clinical Findings

- Common at all ages but in particular during adolescence and pregnancy because of hormonal influences; red, tender gingiva that readily bleeds on brushing or eating (Fig. 7-15).

Etiopathogenesis and Histopathologic Features

Gingivitis and periodontitis result from production of inflammatory cytokines in response to plaque bacterial lipopolysaccharides.

- Loss of normal keratinization may be seen; epithelial hyperplasia with spongiosis and leukocyte exocytosis, as well as plasma cell infiltrate (sometimes intense) in the lamina propria (Fig. 7-16); plaque bacteria often are identified and commonly contain actinomycetes but without clinging neutrophils, and they do not qualify for a diagnosis of actinomycosis (see Actinomycosis in Chapter 4; Fig. 7-17).

Differential Diagnosis

- Plasma cell gingivitis shows intense polyclonal plasma cell infiltrate present in sheets.

Management and Prognosis

- Perform dental scaling, root planing, and prophylaxis to remove plaque; maintain good oral hygiene.

FOREIGN BODY GINGIVITIS

Clinical Findings

- Erythematous or pigmented gingival tissues (if related to amalgam) that may be tender

Etiopathogenesis

Foreign body gingivitis is a reaction to components of dental polishing pastes and amalgam restorations. Energy-dispersive x-ray analysis confirms the presence of silica, aluminium, zinc, calcium, titanium, and barium from dental abrasives from professional polishing pastes, toothpastes, and amalgam.

- Nonspecific acute and chronic inflammation that may be intense; lichenoid or nonnecrotizing granulomatous inflammation in 20% to 48% of cases; fine granules of refractile foreign material (5 microns or less) or amalgam identified (Fig. 7-18); overlying epithelium atrophic or hyperplastic

Differential Diagnosis

- Granulomas in orofacial granulomatosis lack foreign material.

Management and Prognosis

- Steroids reduce inflammation and symptoms, but the foreign material is not readily degradable.
- Surgery may be necessary.

8 Immune-Mediated, Autoimmune, and Granulomatous Conditions

CHAPTER CONTENTS

Granulomatous Inflammation

True granulomas are collections of epithelioid histiocytes with variable inflammation and giant cells. Necrotizing granulomas are often seen in infectious processes and diseases of collagen degradation and necrobiosis. Table 8-1 lists the common granulomatous processes affecting the oral cavity; those caused by infections are discussed in Chapter 4.

FOREIGN BODY GRANULOMAS

Clinical Findings

- Nondescript nodule with a history of trauma; common on lip; related to injection of dermal fillers

Etiopathogenesis and Histopathologic Features

Extrinsic foreign material introduced accidentally (e.g., glass or amalgam filling material) or intentionally (e.g., dermal fillers) excites a histiocytic response. Though generally resorbed, dermal fillers may migrate to sites, distant from the original injection. Foreign body granulomas also form as a reaction to endogenous substances, such as cholesterol from cell membranes, keratin (ruptured epidermal inclusion cysts), and hair (ruptured hair follicle).

- Proliferation of epithelioid histiocytes and foreign body giant cells, nonnecrotizing; refractile or nonrefractile foreign material may be identified (Fig. 8-1).
- Poly-L-lactic acid fillers are refractile fusiform or geometric structures (Fig. 8-2).
- Lipid and silicone granulomas have cytoplasmic vacuoles of varying sizes (Figs. 8-3 and 8-4).
- Calcium hydroxylapatite consists of gray-brown microspheres, 25 to 40 microns in diameter, that are nonrefractile; they stimulate endogenous collagen production and are resorbed within a few months, but they may cause a granulomatous response (Fig. 8-5).
- Foreign body granulomas are common in odontogenic cysts (see Chapter 14), around amalgam tattoos (see Chapter 9), and in keratinizing squamous cell carcinomas (see Chapter 11).

Differential Diagnosis

- Hyaluronic acid fillers appear as amorphous basophilic pools of ground substance that stains for alcian

TABLE 8-1 Types of Granulomatous Inflammation

Granulomatous Inflammation	Distinguishing Features
Reactive	
Foreign body granuloma	Refractile or nonrefractile foreign material present; sometimes foreign material not identified
Intrinsic (e.g., ruptured hair follicle, cholesterol, keratin)	History of trauma or introduction of foreign material
Extrinsic	Dermal filler, amalgam
Infectious	
Bacterial infection (e.g., *Bartonella henselae*)	Warthin-Starry stain
Mycobacterial infection (often necrotizing)	Acid-fast bacillus or Fite stain
Spirochetal infection (e.g., tertiary syphilis gumma)	Warthin-Starry, Dieterle, or modified Steiner stain
Deep fungal infections	Methenamine silver or PAS stain; may see pseudoepitheliomatous hyperplasia
Others	
Sarcoidosis	Hilar lymphadenopathy, elevated ACE levels
Crohn disease	Gastrointestinal symptoms, positive endoscopic findings
Orofacial granulomatosis	Idopathic or related to Crohn disease
Wegener granulomatosis	Upper respiratory or renal findings, c-ANCA positive
Lichenoid granulomatous inflammation	Coexisting lichenoid stomatitis
Palisaded granulomas (e.g., rheumatoid nodule)	History of rheumatoid arthritis or necrobiotic disease

ACE, Angiotensin converting enzyme; *c-ANCA*, cytoplasmic antineutrophil cytoplasmic antibodies; *PAS*, periodic acid–Schiff.

blue and colloidal iron; they do not incite a reaction (Fig. 8-6).

- Palisaded granulomas of necrobiosis lipoidica, granuloma annulare, and rheumatoid arthritis are rarely encountered intraorally.
- Lipid granulomas may resemble atypical lipomatous tumors.

Management and Prognosis

- Excision is curative.

OROFACIAL GRANULOMATOSIS AND CROHN DISEASE

Orofacial granulomatosis may be idiopathic or the first sign of Crohn disease.

Clinical Features

- Generally affects young adults; lips show diffuse or localized rubbery swelling that does not remit (unlike angioedema); tissues feel tight and sore (Fig. 8-7, *A* and *B*).
- May also show concomitant swelling of the gingiva; long-standing cases show cobblestoning and fissuring of mucosa from edema.
- Melkersson-Rosenthal syndrome, in addition to the lip swelling, exhibits fissured tongue and facial palsy; because fissured tongue is very common and facial palsy in this syndrome is very rare, it is unclear if this is a true syndrome.
- Crohn disease—in addition to the aforementioned features, there may also be papular folds of tissue in the maxillary and mandibular sulci, aphthous-like ulcers, gastrointestinal symptoms, and thickened and erythematous appearance of perivermilion skin (see Fig. 8-7, *C*); oral findings precede the diagnosis of intestinal disease in 50% of cases; some patients may also present with pyostomatitis vegetans (see later).

Etiopathogenesis and Histopathologic Features

Orofacial granulomatosis may be seen in patients who are sensitive to foodstuffs such as eggs and chocolate, flavorings including cinnamaldehyde, and preservatives such as benzoates and metabisulfites. Crohn disease is thought to be an inflammatory response possibly to intestinal microbes in genetically susceptible hosts (e.g., polymorphisms in the NOD2/CARD15 genes).

- Nonnecrotizing granulomas are noted and may be subtle in early disease (especially in idiopathic orofacial granulomatosis) (Fig. 8-8) or more florid in later disease; granulomas of Crohn disease may occur in salivary glands and may contain eosinophils (Figs. 8-9 and 8-10); multiple levels should be performed, if necessary, through the entire block to locate granulomas; edema and chronic inflammation alone are not sufficient for the diagnosis.

Differential Diagnosis

- Other granulomatous processes must be ruled out with histochemical stains.

- Granulomas of sarcoidosis are nonnecrotizing and well demarcated or "naked" (Fig. 8-11); patients are often blacks, have hilar lymphadenopathy, and elevated levels of angiotensin-converting enzyme; labial salivary gland biopsies show granulomas in 33% of cases.

Management and Prognosis

- Patch test for the idiopathic type to determine if hypersensitivity to the environment exists; intralesional steroid injections can be done every week for several weeks, but relapse is common; topical, intralesional, and systemic therapy controls disease in 70% of patients; minocycline or thalidomide helps some patients.
- Gastrointestinal work-up is indicated if there are intestinal symptoms.

Pyostomatitis Vegetans

Clinical Findings

- Shallow ulcers and erosions, miliary abscesses and pustules on erythematous mucosa (Fig. 8-12); vegetations may be a feature; sometimes folding and fissuring of the buccal mucosa occurs.
- Most common associations are ulcerative colitis (approximately 70%), Crohn disease (10% to 15%) and liver disease; peripheral blood eosinophilia is present in 90% of cases; some cases are idiopathic.

Etiopathogenesis and Histologic Features

Pyostomatitis vegetans is the oral counterpart of pyoderma vegetans.

- Epithelial hyperplasia, spongiosis, and suprabasilar clefting with acantholysis are present; neutrophilic and eosinophilic abscesses are noted within the clefts and in the connective tissue papillae (Fig. 8-13).
- Direct immunofluorescence studies for immunoglobulin G (IgG) and C3 are negative.

Differential Diagnosis

- Pemphigus vulgaris exhibits intercellular deposition of IgG on direct immunofluorescence studies.

Management and Prognosis

- Oral lesions respond well to topical steroids or tacrolimus (see Appendix A).

Immune-Mediated Conditions

BENIGN MIGRATORY GLOSSITIS (MIGRATORY STOMATITIS; GEOGRAPHIC TONGUE, ERYTHEMA AREATA MIGRANS)

Clinical Findings

- Occurs in 1% to 2% of population, usually in adults
- Well-demarcated, patchy erythematous depapillation of tongue dorsum; raised, linear or circinate, often with discontinuous white peripheral rim; associated with fissured tongue in 25% of cases (Fig. 8-14, *A* and *B*); rare on sites other than the tongue (see Fig. 8-14, *C*)

Etiopathogenesis and Histopathologic Features

There is a strong association with atopy (history of hay fever, eczema, asthma, or food intolerance), and psoriasis (especially pustular forms); some associated with human leukocyte antigen (HLA)-Cw6 (also seen in psoriasis).

- Loss of filiform papillae; psoriasiform epithelial hyperplasia with spongiosis and spongiotic pustules (involving one third to two thirds of the thickness of the epithelium); variable lymphocytic infiltrate (Figs. 8-15 to 8-17)
- Stains for candidal hyphae negative

Differential Diagnosis

- Candidiasis also shows psoriasiform epithelial hyperplasia and spongiotic pustules that are confined to the superficial two to three layers of keratinocytes; candidal hyphae are identified with periodic acid–Schiff stain.
- Spongiotic pustules at the edge of ulcers or in erosions involve the ulcer edge and the superficial keratinocytes.
- Condition is indistinguishable from psoriasis.

Management and Prognosis

- Chronic resolving-relapsing condition
- Pain control with viscous lidocaine and diphenhydramine swish and spit preparation; topical steroids as necessary (see Appendix A)

NONSPECIFIC HYPERSENSITIVITY REACTIONS

Clinical Findings

- Painful erythematous lesions of the oral mucosa with symptoms coinciding with exposure

Etiopathogenesis and Histopathologic Features

Contact hypersensivity reactions are probably within the spectrum of irritant contact stomatitis (see Chapter 7).

- Spongiotic mucositis with benign epithelial hyperplasia, variable chronic inflammation, and eosinophils in the lamina propria and epithelium (Fig. 8-18)

Differential Diagnosis

- Eosinophils and spongiosis seen in nonspecific inflammatory lesions

Management and Prognosis

- Avoidance of inciting agent; topical steroids to resolve lesions (see Appendix A)

ERYTHEMA MULTIFORME

Erythema multiforme is an acute, self-limited, inflammatory mucocutaneous disease that manifests on the skin; it often involves the oral, ocular, and genital mucosa.

Clinical Findings

- Affects adults between 20 to 40 years of age; 20% are children; history of viral infection, specifically herpes simplex virus infection, several weeks earlier
- Pruritic, itchy red papules on face, neck, and extremities that progress centripetally toward the trunk over days with postinflammatory hyperpigmentation; ring-like "target" or "iris" lesions typical, especially on the palms
- Oral lesions in 25% to 70% of patients; diffuse painful erythema or ulcerations affecting the mucosa; chronic oral erythema multiforme reported without involvement of skin (Fig. 8-19)
- Minor type: less than 10% skin involvement with little-to-no mucous membranes affected; major type: more extensive skin involvement with mucous membranes affected
- Stevens-Johnson syndrome, a more severe form of toxic epidermal necrolysis, is more often a drug-induced hypersensitivity reaction or hypersensitivity to *Mycoplasma pneumoniae* and is no longer considered synonymous with severe erythema multiforme.

Etiopathogenesis and Histopathologic Features

Erythema multiforme is often a hypersensitivity reaction to herpes simplex virus (in at least 50% of cases); other cases result from reactions to nonsteroidal anti-inflammatory drugs, anticonvulsants, or benzoic acid.

- Hydropic degeneration of basal cells, leukocyte exocytosis, keratinocyte apoptosis and necrosis, and sometimes subepithelial bulla formation occur, although these features vary depending on the stage of the lesion; hallmark in skin biopsies is lymphocyte satellitosis around necrotic keratinocytes; variable lymphohistiocytic infiltrate appears in lamina propria and around vessels; usually no eosinophils are present unless the condition is drug associated (Fig. 8-20).

Differential Diagnosis

- Lichen planus and contact hypersensitivity reactions may appear similar and are differentiated by history and clinical findings; contact stomatitis usually shows eosinophils.

Management and Prognosis

- Mild disease is managed with supportive care and systemic or topical analgesics for pain because it is self-limiting and resolves within a few weeks; more severe cases are usually managed with systemic and topical corticosteroids (see Appendix A).
- Treatment with acyclovir at the first sign of disease in recurrent erythema multiforme controls disease in approximately 50% of the patients.

PLASMA CELL ORIFICIAL MUCOSITIS (PLASMA CELL STOMATITIS, MUCOUS MEMBRANE PLASMACYTOSIS)

Clinical Findings

- Brightly erythematous, sometimes nodular gingival hyperplasia occurs (Fig. 8-21); other mucosal sites and mucosa of the upper airway may be involved; localized plaques and cobblestoning may be present, and fissuring of the corners of the mouth and swollen lips are often noted.

Etiopathogenesis and Histopathologic Features

Hypersensitivity reaction to contactant such as chewing gum, toothpaste, or other contactant.

- Loss of normal keratinization, epithelial hyperplasia with spongiosis, and leukocyte exocytosis; intense plasma cell infiltrate (polyclonal) within the lamina propria (Figs. 8-22 and 8-23); Russell bodies and lymphocytes may be seen.

Differential Diagnosis

- Banal gingivitis and periodontitis are usually associated with multifocal plasma cell infiltrates that are less dense; clinical findings are important in differentiating these lesions.
- Plasmacytomas show monoclonal plasma cell proliferation with light chain restriction.

Management and Prognosis

- Identify and discontinue contactant; topical steroid therapy may be helpful (see Appendix A).

LICHEN PLANUS/LICHENOID MUCOSITIS

Although considered an autoimmune condition by some, the target antigen has yet to be identified.

Clinical Findings

- This condition occurs in 1% to 2% of adults, usually women in middle age; lesions are generally bilateral and symmetric.
- Three presentations are noted, often in combination: *reticular/keratotic* (classic)—white striations or papules, not usually painful, appear on the buccal mucosa, ventral and dorsal tongue, labial mucosa, and gingiva (Fig. 8-24, *A*); *erythematous/erosive*—red areas of the mucosa, particularly on the gingiva, that look raw and are painful (desquamative gingivitis) (see Fig. 8-24, *B* and *C*); *ulcerative*—yellow fibrin membrane (see Fig. 8-24, *D*); postinflammatory hyperpigmentation is noted in dark-skinned individuals (see Fig. 8-24, *E*); lesions on the tongue result in atrophy of filiform papillae and may not be well reticulated (see Fig. 8-24, *F*).
- Skin involvement is present in 10% to 15% of patients (see Fig. 8-24, *G*); vulvovaginal-gingival and penogingival lichen planus are usually associated with the desquamative form of the condition and with buccal mucosa fibrosis occurring in a minority of patients.
- Chronic graft-versus-host disease after allogenic stem cell transplantation has a similar appearance, but presence of plaques should raise suspicion for proliferative leukoplakia (see Fig. 8-24, *H*)
- Granulomatous lichenoid mucositis tends to affect the upper labial mucosa as macular erythema (see Fig. 8-24, *I*)
- Demarcated white plaques that develop within lichen planus should always be biopsied; often, leukoplakias or erythroleukoplakias are mistakenly diagnosed as plaque-type lichen planus leading to the perception of high incidence of malignant transformation reported in the literature; solitary white plaques should not be considered plaque-type lichen planus but rather leukoplakia.

Etiopathogenesis and Histopathologic Features

Lichen planus and lichenoid reactions are a final common pathway of tissue reaction characterized clinically by reticulated keratosis and variable erythema and histologically by T cell destruction of the basal cells; tumor necrosis factor-α plays an important role. It is not possible to distinguish by histopathology among idiopathic lichen planus, lichenoid hypersensitivity reactions related to medications (such as hydrochlorothiazide

and other antihypertensive agents, carbamazepine, allopurinol, sulfasalazine, and some monoclonal antibodies), contact lichenoid reactions to dental amalgams, or lichen planus associated with hepatitis C. The degree to which histopathologic features manifest depends on the stage of the lesion and whether the lesion has been treated. Cutaneous disease is associated with a higher incidence of HLA-DRB1*0101, and vulvovaginal-gingival syndrome may be associated with HLA-DQB1*0201. HLA-DR6 is seen in higher incidence in Italians with hepatitis C–associated lichen planus.

- Two most important criteria: degeneration and loss (squamatization) of the basal cell layer and a lymphocytic band of variable thickness at interface with blurring of interface; lesions may be parakeratotic or orthokeratotic, and epithelium may be hyperplastic or atrophic (Figs. 8-25 and 8-26).
- Spongiosis, leukocyte exocytosis, colloid (Civatte or cytoid) body formation, sawtooth rete ridges, postinflammatory hypermelanosis, thickened basement membrane zone, increased numbers of Langerhans cells, and subepithelial clefting are variable findings; clefting is a reliable artifact and is caused by lack of basal cell adhesion to the lamina propria rather than necessarily representing a clinical blister (Figs. 8-27 to 8-29).
- Plasma cells often are noted in the vicinity of an ulcer or in gingival lesions; eosinophils may be seen and hypersensitivity reaction should be considered if present in large numbers, especially within the epithelium.
- Granulomatous lichenoid lesions (on the labial mucosa) exhibit many histiocytes in the lamina propria (Figs. 8-30 and 8-31).
- The terms *lichenoid stomatitis* and *mucositis* are often used if not all of the features are seen or if they are subtle; such lesions may be waxing or waning or result from therapy (Fig. 8-32).
- Direct immunofluorescence shows shaggy fibrinogen in stalactite pattern at basement membrane zone, and IgM staining of colloid bodies and basement membrane zone (Fig. 8-33); granular (not linear) C3 deposition may be seen.
- Lichenoid hypersensitivity reactions are indistinguishable histologically from idiopathic lichen planus.
- A particular contact hypersensitivty reaction is cinnamic aldehyde–associated lichenoid mucositis characterized by a dense lymphohistiocytic infiltrate at the interface and perivascular and paravascular lymphoid aggregates (these should not be interpreted as vasculitis) (Fig. 8-34).

Differential Diagnosis

- Epithelial dysplasia (and carcinoma) often exhibits a lymphocytic band at the interface associated with hyperplasia (not loss) of the basal cell layer (see Chapter 11); use of term *lichenoid dysplasia* is misleading and should be avoided.
- Chronic graft-versus-host disease has muted features of lichen planus and the lymphocytic band is usually sparse because of immunosuppression (Fig. 8-35).
- Lupus erythematosus shows hydropic degeneration of basal cells, alternating epithelial atrophy and hyperplasia, a lymphocytic band at the interface, and linear IgG at the interface on direct immunofluorescence.
- Mucous membrane pemphigoid exhibits preservation of the basal cells (see later).
- Chronic ulcerative stomatitis (a condition that histologically resembles erosive lichen planus) exhibits antibodies directed against δNp63α, an isoform of p63 in the nucleus of epithelial cells; direct immunofluorescence studies using monkey esophagus shows speckled nuclear staining; indirect immunofluorescence using guinea pig esophagus demonstrates nuclear reactivity particularly well.
- Rare cases of lichen planus pemphigoides have been reported, possibly resulting from epitope spread.

Management and Prognosis

- Management of symptomatic lesions is with episodic topical antiinflammatory therapy (see Appendix A); tumor necrosis factor inhibitors may resolve lesions (but may also precipitate them).
- Changing antihypertensive medications may not be helpful, because most classes of such medications may result in these lesions.
- Malignant transformation of lichen planus is controversial (likely 0.1% to 0.2%); some cases of histologic dysplasia with a lymphocytic band at the interface (a frequent occurrence) is misdiagnosed as lichen planus with reactive atypia, and these lesions progress to carcinoma; conversely, cases of lichen planus with reactive atypia (a frequent occurrence) are diagnosed as lichenoid dysplasia.
- Replacing amalgam restorations in patients with demonstrated hypersensitivity to amalgams resolves lesions.

Autoimmune Conditions

The two autoimmune diseases that often present in the oral mucosa are mucous membrane pemphigoid (by far the more common) and pemphigus vulgaris, and a common clinical presentation is desquamative gingivitis (generalized red, denuded gingiva), similar to lichen planus. Other autoimmune diseases such as lupus erythematosus, linear IgA disease, and epidermolysis bullosa acquisita rarely manifest in the mouth in the absence of skin lesions.

MUCOUS MEMBRANE PEMPHIGOID

Mucous membrane pemphigoid is a heterogeneous group of subepithelial blistering disorders with autoantibodies directed against a number of antigens, depending on the presentation.

Clinical Findings

- Pemphigoid usually occurs in middle-aged females.
- Painful, bleeding gums are reported, especially when brushing teeth; desquamative gingivitis is the most common presentation with bright red, denuded, painful, and tender gingiva (usually on the buccal or facial aspect) (Fig. 8-36, *A*); ulcers are uncommon on other sites without gingival involvement; remnants of necrotic blister roof appears as pseudomembrane.
- Approximately 70% to 80% of all cases of desquamative gingivitis represent either mucous membrane pemphigoid or lichen planus; the rest are other autoimmune blistering diseases or oral hypersensitivity reactions (see Fig. 8-36, *B*).

Etiopathogenesis and Histopathologic Features

Primary mucosal disease generally involves BP180 (BPAg2), less often BP230 (BPAg1), laminin-332 (formerly laminin-5 or epiligrin), and β4 subunit of α6β4 integrin; oral and ocular pemphigoid are associated with increased frequency of HLA-DQB1*0301.

- Subepithelial clefting is noted with preservation of basal cells that protrude into the cleft; epithelium may be hyperplastic or atrophic and generally lacks spongiosis; biopsies often show only detached fragments of epithelium with intact basal cells (Figs. 8-37, 8-38 and 8-39); lamina propria shows variable lymphocytic infiltrate; eosinophils are uncommon.
- Direct immunofluorescence studies show linear IgG, C3, and/or IgA at the basement membrane zone (Fig. 8-40).
- Circulating antibodies manifest in less than half the cases; immunoreactants localize to the roof of the lesion in salt split skin technique.

Differential Diagnosis

- Lichen planus shows subepithelial clefting, as well as degeneration or squamatization of basal cells, colloid bodies, and sawtooth rete ridges.
- Presence of linear IgA on direct immunofluorescence should **not** be interpreted as primary linear IgA bullous disorder, unless there are typical skin lesions of linear IgA bullous dermatosis, bullous dermatosis of childhood, or dermatitis herpetiformis associated with celiac disease.
- Paraneoplastic pemphigoid has been reported in cases of lymphoma and renal cell carcinoma, but these may represent paraneoplastic autoimmune multiorgan syndrome (see later).
- Lichen planus pemphigoides, and the simultaneous development of autoantibodies against pemphigus vulgaris, occur because of epitope spread.
- Angina bullosa hemorrhagica manifests with intact basal cells, hemorrhage within subepithelial bulla and granulation tissue, and exhibits a typical clinical history of waxing and waning hemorrhagic bullae with a history of chronic steroid inhaler use.

Management and Prognosis

- Topical steroids are the mainstay of treatment with or without up-front systemic steroid therapy to rapidly bring disease under control (see Appendix A); a stent used to hold the steroid under occlusion is particularly helpful (Fig. 8-41); topical or systemic analgesia is used for pain control; patient should see an ophthalmologist and dermatologist to evaluate for conjunctival and skin lesions.
- Dapsone is particularly effective for mucous membrane pemphigoid; alternative therapies include niacinamide and vitamin B or etanercept.

PEMPHIGUS VULGARIS

Clinical Findings

- Condition occurs in middle-aged and older patients, often of Ashkenazi-Jewish descent; genetic susceptibility associated with HLA-DRB1 (*0402)-DQB1 (*0503) in whites in the United States; Asians may show association with HLA-DRB1 (*0403 and *0406); other putative associations may be a result of linkage disequilibrium.
- Painful ulcers and shallow erosions occur, characteristically on the hard and soft palate; a necrotic blister roof appears as a pseudomembrane; desquamative gingivitis is often present (Fig. 8-42, *A-D*).
- Oral findings often precede skin findings (flaccid bullae and erosions) or may be the only manifestation (see Fig. 8-42, *E*).
- Pemphigus may be induced by medications such as penicillamine and angiotensin-converting enzyme inhibitors.

Etiopathogenesis and Histopathologic Features

Antibodies are directed against desmoglein-3 in oral pemphigus vulgaris, and also against desmoglein-1 if there is mucocutaneous disease. Pemphigus foliaceus (including fogo selvagem, the endemic form), and pemphigus erythematosus (features of pemphigus foliaceus and lupus erythematosus) do not usually present in the mouth. The quantity of antibody and antigen to which it is directed dictates clinical presentation.

- Suprabasilar cleft with rounded acantholytic cells appear; there is variable chronic inflammation in the lamina propria (Figs. 8-43 and 8-44).
- Direct immunofluorescence shows intercellular deposition of IgG (Fig. 8-45); intercellular staining for IgA may also be seen and up to two thirds of patients show circulating IgA antibodies against desmoglein-3; epitope spread may account for the production of antibodies against multiple antigens.
- Indirect immunofluorescence findings are seen in cases with more severe disease; antibody levels correlate with disease activity and are useful data for monitoring response to therapy.

Differential Diagnosis

- Pyostomatitis vegetans shows acantholysis and eosinophilic abscesses that are negative on immunofluorescence; patients have inflammatory bowel disease.
- Darier disease and warty dyskeratoma show dyskeratosis and, with benign familial pemphigus (Hailey-Hailey disease), are negative on direct immunofluorescence.
- Focal acantholytic dyskeratosis is seen as an incidental finding, especially on the lip lesions.
- Pseudoacantholysis is seen as suboptimal fixation artifact; cells are not rounded but rather are angulated (Fig. 8-46).
- IgA pemphigus rarely affects the oral mucosa and exhibits deposition of IgA intercellularly, with circulating IgA directed against desmocollins and desmogleins.

Management and Prognosis

- Circulating levels of IgG are helpful for monitoring response to therapy; however, patients with oral findings usually do not have significant levels of serum IgG.
- Oral disease may be successfully treated with topical steroids combined with initial systemic therapy to bring disease under control (see Appendix A); pain is controlled with topical or systemic analgesics.
- Mycophenolate as monotherapy, or multiagent therapy is combined with prednisone, rituximab, and intravenous immunoglobulin therapy.

PARANEOPLASTIC PEMPHIGUS

Paraneoplastic pemphigus is an uncommon disorder and a paraneoplastic syndrome. Some have proposed that the term *paraneoplastic autoimmune multiorgan syndrome* may be more appropriate, because lesions may resemble to a larger or smaller extent pemphigus, pemphigoid, lichen planus, or erythema multiforme with multiorgan involvement. Paraneoplastic pemphigus is associated with HLA-DRB1*03 in whites and Cw*14 in Chinese patients.

Clinical Findings

- Extensive painful ulcers and erosions of the oral cavity with hemorrhagic crusts on the lips appear similar to Stevens-Johnson syndrome (Fig. 8-47).
- Skin lesions are poikilodermic, lichenoid, or blistering, and biopsies are usually taken from the skin owing to ease of access.
- Non-Hodgkin lymphoma (40%), chronic lymphocytic leukemia (30%), Castleman disease (10%), thymoma (6%), sarcoma (6%), Waldenström macroglobulinemia (6%), and other malignancies are associated with this disorder; it is not usually associated with carcinoma.

Etiopathogenesis and Histopathologic Features

One hypothesis for this disease is that dysregulated cytokine production by tumor cells drives the development of autoimmunity with antibodies produced by the host. Damage is mediated by autoantibodies and T cell–mediated cytotoxicity. Autoantibodies are directed against desmoglein-1 and -3, envoplakin, periplakin, and desmoplakin for the most part. Other antigens include BP 230 (BP Ag1), plectin, and plakoglobin.

- Suprabasilar clefting occurs with acantholysis, and interface stomatitis with lichenoid lymphocytic band and subepithelial clefting are evident.

- Direct immunofluorescence shows intercellular, linear, and granular subepithelial deposits of IgG and C3 and sometimes IgM; positive indirect immunofluorescence studies using rat bladder epithelium are diagnostic.
- Western blotting and immunoprecipitation identify the specific antibodies.

Management and Prognosis

- A search for and identification of underlying malignancy is of utmost importance, although treatment of the malignancy may not always halt progression of mucocutaneous disorder.
- Systemic therapy consists of high-dose prednisone, cyclophosphamide, rituximab, cyclosporine, and intravenous immunoglobulin, although oral disease may be refractory; involvement of the lung leads to significant morbidity, and respiratory failure is often a terminal event.

LUPUS ERYTHEMATOSUS

Discoid and systemic lupus erythematosus are commonly associated with oral lesions.

Clinical Findings

- Disease affects predominantly females; oral lesions rarely occur in the absence of skin lesions, which vary depending on the subtype—the three most common being systemic, subacute, and discoid; photodistributed "butterfly rash" on the malar region is typical for systemic lupus erythematosus; scaly and atrophic plaques with follicular plugging and postinflammatory hyperpigmentation is common in discoid lupus erythematosus (Fig. 8-48, *A* and *B*).
- Oral disease presents as aphthous-like ulcers or reticulated and erythematous (lichenoid) lesions on the buccal mucosa or as erythematous macules and keratotic plaques on the palatal or labial mucosa; up to 20% and 45% of patients with discoid and systemic lupus erythematosus, respectively, have oral lesions (see Fig. 8-48, *C* and *D*).
- Keratoconjunctivitis sicca may develop if there is concomitant secondary Sjögren syndrome.

Etiopathogenesis and Histopathologic Features

Lupus erythematosus is an autoimmune disease that may show multiorgan involvement. Antibodies are directed against double-stranded DNA (dsDNA).

- Both epithelial hyperplasia and atrophy with vacuolar degeneration of basal cells, bandlike lymphocytic infiltrate at the interface, and deep perivascular and paravascular lymphocytic infiltrates occur; thickening of epithelial and vascular basement membranes appears.

- Direct immunofluorescence studies show a positive lupus band test or linear/granular deposition of IgG, IgM, or IgA at the basement membrane; a positive lupus band test for clinically normal skin is strongly predictive of systemic lupus erythematosus.
- Antinuclear antibody, anti-dsDNA, antiribonucleoproteins and anti-Ro antibodies are usually present.

Differential Diagnosis

- Cinnamic aldehyde contact stomatitis exhibits a lymphocytic band at the interface and deep perivascular and paravascular infiltrates, but not usually hydropic degeneration of basal cells, and it has negative lupus band test.
- Lichen planus does not show positive immunofluorescence for linear IgG.

Management and Prognosis

- Topical and/or systemic therapy for mucosal lesions depending on the severity (see Appendix A).

WEGENER GRANULOMATOSIS

Wegener granulomatosis falls under the larger category of antineutrophil cytoplasmic autoantibody (ANCA)–associated vasculitides that also include microscopic polyangiitis, Churg-Strauss syndrome, and renal-limited vasculitis. Wegener granulomatosis is associated with HLA-DPB1.

Clinical Findings

- Affects adults; oral findings are the first presentation in approximately 6% to 13% of patients; limited form of the disease affects only the upper airways and oral cavity.
- Painful, necrotic ulcers of the oral mucosa, in particular the hard palate, manifest as "midline destructive disease" (Fig. 8-49, *A*); gingiva is hyperplastic with a friable, pebbly, and erythematous appearance and pinpoint hemorrhage characteristic for vasculitides ("strawberry gingivitis") (see Fig. 8-49, *B*).
- Nasal carriage of *Staphylococcus aureus* is associated with increased risk for relapse.

Etiopathogenesis and Histopathologic Findings

Wegener granulomatosis is a small- and medium-vessel necrotizing vasculitis that in its full expression affects the upper respiratory tract and oral mucosa, lungs, and kidneys (necrotizing glomerulonephritis).

- Edema of lamina propria with mixed acute and chronic inflammatory infiltrate with variable geographic necrosis; necrotizing granulomas are noted although vasculitis may be difficult to identify (Fig. 8-50)
- Indirect immunofluorescence testing reveals the presence of ANCA in a cytoplasmic (cANCA) or perinuclear (pANCA) pattern with enzyme-linked immunosorbent assay (ELISA) positivity for antibodies against proteinase-3 and myeloperoxidase, respectively.

Management and Prognosis

- High-dose prednisone and cyclophosphamide for several months is a mainstay of therapy; methotrexate, azathioprine, and mycophenolate mofetil mitigates toxicity of prolonged cyclophosphamide use; rituximab is useful for refractory cases.
- Surgical reconstruction may be necessary if there has been extensive tissue destruction.

9 Pigmented Lesions

CHAPTER CONTENTS

Exogenous Pigmentation

AMALGAM TATTOO

Clinical Features

- Amalgam tattoo is localized (usually < 1 cm) or, less commonly, diffuse; it is a slate-gray macule of oral mucosa and is nontender and evenly pigmented.
- Tattoo often appears on gingiva adjacent to amalgam restorations or crowns, but it may be on any surface and, in particular, after apicoectomy (root apex surgery) with amalgam retrofill (Fig. 9-1, *A-C*).

Etiopathogenesis and Histopathologic Features

Silver within amalgam (combination of silver, mercury, tin, and other metals) stains agyrophilic reticulin fibers of connective tissue. It either leaches out of contacting amalgams or root canal fillings, or is traumatically implanted.

- Scar is often present (especially if lesion is not adjacent to an amalgam) with variable lymphocytic infiltrate (Fig. 9-2, *A*).
- Fine golden-brown particles are deposited in a "beaded" pattern along connective tissue fibers and basement membrane of epithelium and blood vessels.
- Reticulin fibers, endomysium, and endoneurium may be stained golden-brown with no particulate deposits; larger particles often are found within foreign body granulomas (see Fig. 9-2, *B-E*; Figs. 9-3 and 9-4).
- Refractile crystalline foreign material may be seen occasionally in traumatically implanted lesions; this likely represents fragments of dental cement placed with amalgams.

Differential Diagnosis

- Medication-induced pigmentation exhibits fine particles that align in linear fashion between collagen fibers, but they do not stain the fibers; usually they are Fontana-Masson and/or iron positive (see later).

Management and Prognosis

- Surgical or laser removal is curative and is performed for cosmetic reasons.

GRAPHITE TATTOO

Clinical Findings

- Localized gray-to-black, nontender macule on any mucosal site but often on palate (e.g., child who falls when running with a pencil held between the teeth, puncturing the palate)

Etiopathogenesis and Histopathologic Features

This is caused by traumatic implantation of pencil graphite.

- Coarse black granules of nonrefractile, slightly geometric, foreign material, some of which lie within multinucleated giant cells of foreign body granulomas; no distinguishing features so history important in diagnosis (Fig. 9-5)

Differential Diagnosis

- Unlike amalgam, it is slightly birefringent, maintains birefringence after treatment with 10% ammonium sulfide, and does not stain connective tissue fibers.
- Other traumatically-implanted foreign bodies should be considered, and the diagnosis should be elicited by a careful history taking (Fig. 9-6).

Management and Prognosis

- Excision or no treatment

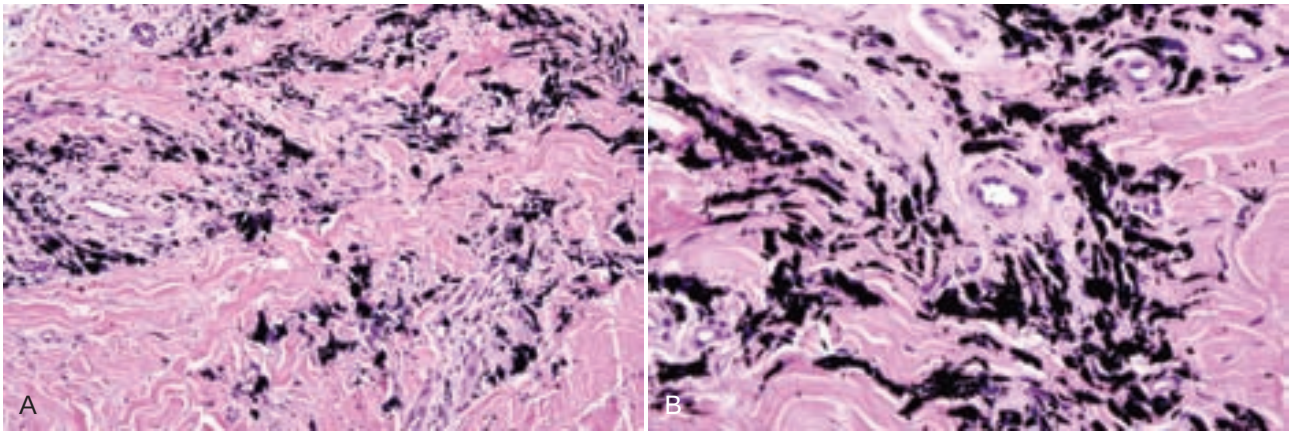

FIGURE 9-6. Graphite tattoo. **A,** Black particulate foreign material with fibrosis. **B,** Large and small black particles without staining of collagen.

MEDICATION-INDUCED PIGMENTATION

Clinical Findings

- Diffuse, painless, symmetric, bluish-gray macular pigmentation of the hard palate; patient may have concomitant skin lesions (Fig. 9-7).
- Patient on minocycline, antimalarial medications (such as mepacrine or quinacrine), birth control pills, clofazimine, and imatinib are susceptible.
- Tetracycline and its analogues are taken up by teeth and bone, which appear brown, and this is visible through the oral mucosa.

Etiopathogenesis and Histopathologic Features

Condition is caused by break-down products of the medication that chelate with iron or melanin.

- Particles are brown, spherical, uniform, only a few microns in diameter, and they tend to align in linear fashion between collagen fibers, although this may represent pigment within dendritic processes of macrophages; particles are often present within macrophages (Fig. 9-8, *A-D*).
- Staining is positive with Prussian blue for iron and Fontana-Masson for melanin, although degree of staining is variable (see Fig. 9-8, *E*); usually elicits no fibrosis or inflammation.
- Teeth are stained by tetracycline fluoresce under polarized light.

Differential Diagnosis

- Amalgam is not spherical, and it stains the collagen fibers.
- Hemosiderin particles are larger, coarser, and more variable in size and stain with Prussian blue stain (Fig 9-9).
- Melanin is not as uniform, and it is often present concomitantly within basal cells.
- Rare instances of pigmentation caused by leaching of metals from a denture have been reported.

Management and Prognosis

- No treatment is necessary unless there is cosmetic concern, in which case laser ablation may be helpful.

Melanocytic Pigmentation

Physiologic pigmentation is very common on the gingiva and other mucosa of dark-skinned individuals and is generally bilaterally symmetric and evenly pigmented (Fig. 9-10, *A*).

The two most common melanocytic lesions in the oral cavity are oral melanotic macule (comprising more than 80% of melanotic lesions) and postinflammatory hypermelanosis. Some melanotic macules are likely to represent end-stage postinflammatory hyperpigmentation. The less common melanoacanthosis also represents postinflammatory pigmentation.

ORAL MELANOTIC MACULE

Clinical Findings

- Macules are seen in adults, usually in the fifth decade, but rarely, they may occur congenitally on the tongue.
- Discrete, brown-to-tan-to-black, painless macules are usually evenly pigmented, less than 1 cm, usually on the lower vermilion, palate, or gingiva (see Fig. 9-10, *B* and *C*).
- The macule is most often solitary but may be multifocal, especially in the Laugier-Hunziker syndrome (with melanonychia) (see Fig. 9-10, *D*)
- Unlike ephelides, they do not darken with exposure to sunlight.

Etiopathogenesis and Histopathologic Features

Some melanotic macules may represent postinflammatory hypermelanosis, but others are idiopathic.

- Increased melanin occurs within basal cells in the absence of or with minimal melanocytic hyperplasia; with incontinent melanin and melanophages in lamina propria; melanin is most prominent in the lower half of the epithelium and at tips of rete ridges (Figs. 9-11 and 9-12).
- Variable vascular ectasia and absent-to-mild lymphocytic infiltrate may be evident.
- Overlying epithelium usually shows mild acanthosis.

Differential Diagnosis

- Postinflammatory hypermelanosis appears similar with obvious inflammation present; melanotic macule may represent end stage of postinflammatory changes.
- Melanoacanthosis shows acanthosis with dendritic melanocytes present throughout the thickness of the epithelium.
- Rule out Addison disease if onset of multiple melanotic macules is sudden.
- Melanotic macules are present in lentigines syndromes, such as neurofibromatosis, Peutz-Jeghers syndrome, McCune-Albright syndrome, Carney syndrome complex, and Bannayan-Ruvalcaba-Riley syndrome.

Management and Prognosis

- No treatment is necessary; laser ablation may be helpful if there are cosmetic concerns.
- Most cases are not followed up, and it is unclear if the macules disappear over time.

POSTINFLAMMATORY HYPERMELANOSIS

Clinical Findings

- Associated with nonspecific inflammation or known inflammatory disease, especially lichen planus, history of significant antecedent inflammation (such as postradiation mucositis and postchemothecapy mucositis), or a smoking habit (smoker's melanosis).
- Diffuse pigmentation appears on the involved mucosa in the area of the underlying inflammatory condition (Fig. 9-13); pigmentation may also be discrete if associated with localized inflammation.

Etiopathogenesis and Histopathologic Features

Inflammatory lesions and, in particular, lichenoid lesions often result in perturbation of melanocytes in the epithelium, causing increased melanin deposition.

- Increased melanin pigment within basal cells with no or mild benign melanocytic hyperplasia; incontinent melanin, melanophages, and inflammation in the lamina propria (Figs. 9-14 and 9-15) occurs; infrequently, there is benign melanocytic hyperplasia (Fig. 9-16); some lesions resemble early melanoacanthosis (Fig. 9-17).
- Inflammatory process is evident (e.g., lichenoid mucositis or nonspecific chronic inflammation) (Fig. 9-18).

Differential Diagnosis

- Condition likely overlaps with melanoacanthosis if significant melanocytic hyperplasia is present (see Fig. 9-17, *B*).

Management and Prognosis

- Even with treatment of the underlying inflammatory condition with topical steroid therapy, it takes many months for the pigmentary changes to fade.

MELANOACANTHOSIS (MELANOACANTHOMA)

The term *melanoacanthosis* is preferable to *melanoacanthoma* because this macular lesion is not a tumorlike proliferation and is clinically distinct from cutaneous melanoacanthomas that occur in older white patients as plaques or nodules.

Clinical Findings

- Melanoacanthosis occurs fairly rapidly (days to a few weeks); painless, tan-brown macules may be solitary (80%) or multifocal and are usually greater than 1 cm; they usually occur in young adult black females (Fig. 9-19); most common location is buccal mucosa (50%), followed by the palatal mucosa and lips.

Etiopathogenesis and Histopathologic Features

This condition is likely a form of postinflammatory hypermelanosis (see earlier).

- Proliferation of benign dendritic melanocytes located throughout the full thickness of the acanthotic epithelium; minimal surface keratinization and spongiosis; increased melanin within basal cells; melanin, melanophages, and variable chronic inflammation in the lamina propria (Figs. 9-20, 9-21, *A* and *B* and 9-22)
- Melanocytes positive for S-100, Melan-A, and HMB-45 (see Fig. 9-21, C)

Differential Diagnosis

- Lack of melanocytic atypia rules out an atypical melanocytic proliferation or melanoma in situ despite transmigration of melanocytes.

Management and Prognosis

- No treatment is necessary; lesions will likely fade over time.

ORAL MELANOCYTIC NEVUS

Clinical Findings

- Most are noted in the third to fourth decade of life.
- Frequency is as follows: intramucosal nevi (64% to 80%), blue nevi (8% to 17%), and compound (6% to 17%); junctional and combined nevi are rare.
- Intramucosal, compound, and combined nevi tend to be plaques or nodules, and blue and junctional nevi are macules or plaques (Fig. 9-23); plaque-type blue nevus is a distinct subtype of blue nevus.
- Common sites are palatal mucosa (34% to 44%), mucobuccal fold (24%), buccal mucosa (11% to 22%), lip vermilion (18%), and gingiva (12% to 23%).

Etiopathogenesis and Histopathologic Findings

Oral melanocytic nevi are hamartomas that derive from nevomelanocytes cells that originate from the neural crest.

- Intramucosal nevus: nests and theques of epithelioid cells (type A) just beneath the epithelium with variable pigment content, often heavily pigmented near surface; lymphocyte-like (type B) or neuroid spindle cells (type C) deeper in the lamina propria; slight junctional activity acceptable for intramucosal nevus; may see significant nuclear-shaped pleomorphism, but chromatin dispersed without mitotic activity (Figs. 9-24 to 9-26)
- Junctional nevus: many nests of benign nevus cells in the basal layer
- Compound nevus: combination of intramucosal and junctional nevus (Fig. 9-27)
- Blue nevus: spindled nevus cells with benign nuclei without junctional nests; usually heavily pigmented; epithelioid variant seen; nonpigmented spindle cells HMB-45 positive, and like skin lesions may be S-100 negative (Figs. 9-28 and 9-29)
- Combined nevus: presence of both intramucosal and blue nevus usually without superficial nesting (Figs. 9-30 and 9-31)
- Rare cases of balloon cell nevus reported
- Cells positive for S-100 protein, Melan-A, and HMB-45

Differential Diagnosis

- Amalgam tattoo differs from blue nevus because of deposition of pigment granules along connective tissue fibers and is negative for melanocytic markers.
- Medication-induced pigmentation exhibits regular spherical granules that stain for iron and is negative for melanocytic markers.
- Dysplastic nevus and malignant melanoma show cytologic atypia; oral melanoma almost always has an intraepithelial dysplastic melanocytic component; metastatic melanoma to the oral mucosa will not show an in situ component.

Management and Prognosis

- Excision is curative and lesions do not recur. Remnant lesions after incisional biopsy do not require excision.

DYSPLASTIC MELANOCYTIC NEVUS AND MUCOSAL MELANOMA

Clinical Findings

Head and neck melanoma constitutes 1% to 8% of all melanomas; it is much more common in the sinonasal tract than in the oral cavity, and it is more common in blacks and Japanese. It tends to occur in older patients compared with skin melanomas.

- Occurs in fifth to seventh decade of life with male predilection; usually on the palatal mucosa, gingiva, or lip.
- Melanoma arises within a dysplastic melanocytic lesion similar to acral lentiginous melanoma (Fig. 9-32).
- Melanomas are usually greater than 1 cm and are irregularly pigmented with irregular borders; nodularity and areas of hemorrhage should arouse suspicion.

Etiopathogenesis and Histopathologic Features

Because the oral cavity is not exposed to the sun, oral melanomas are of unclear etiopathogenesis, and they behave in a similar fashion to acral lentiginous melanoma.

- Dysplastic melanocytic nevus or in situ melanoma: proliferation of atypical melanocytes within the epithelium either in lentiginous or pagetoid fashion; retraction artifact seen in melanocytes and nests (Fig. 9-33, *A*)
- Melanoma: atypical spindled or epithelioid melanocytes within lamina propria; large nuclei, prominent nucleoli, and pseudoinclusions in epithelioid cells (Figs. 9-34, *A-C*, 9-35, *A-C*; see Fig. 9-33, *B* and *C*); up to 40% amelanotic; transepithelial migration of atypical melanocytes characteristic (see Figs. 9-34, *D*, 9-35, *D*); cells S-100 protein positive, HMB-45 positive, Melan-A positive, and cytokeratin negative (see Fig. 9-34, *E*)
- Level I: in situ lesion or microinvasion only; level II: invasion into the lamina propria only; level III: invasion into the deep structures (such as muscle, bone, or cartilage); Clark's levels and Breslow thickness not useful for prognostication
- Sarcomatoid features, pseudopapillary architecture and undifferentiated cells, thickness greater than 5 mm, and vascular invasion associated with poor survival

Differential Diagnosis

- Poorly differentiated spindled and epithelioid malignancies are differentiated from melanoma based on positive identification of cytoplasmic S-100 protein, HMB-45, Melan-A, and negativity with cytokeratin.

Management and Prognosis

- Excision with clear margins is the treatment of choice; recurrence rate is 50%; adjuvant radiotherapy reduces local relapse and metastases, but it may not improve survival.
- Stage 1 disease with level I and III invasion have median survival of 138 and 117 months, respectively.
- Nodal and distant metastases occur in 24% and 44% of cases, respectively, and 5-year survival is 20% to 30%.
- Chemotherapeutic regimens, including the use of interferon, are still under investigation.

Neuroectodermal Pigmentation

MELANOTIC NEUROECTODERMAL TUMOR OF INFANCY

Clinical Findings

- Most cases manifest in the first 6 months of life, and more than 90% occur in the head and neck; slight male predilection (1.5:1) and is the most common site (60%) (Fig. 9-36); extraoral cases are more common in children older than 1 year.
- Tumor grows rapidly and consists of a brownish-red, mass of the alveolar mucosa with a radiolucency within the bone.
- Vanillylmandelic acid is increased in urine.
- Lymph node or distant metastases occur in 3% to 7% of cases.

Etiopathogenesis and Histopathologic Features

Melanotic neuroectodermal tumor of infancy is likely to derive from tissues of neural crest origin.

- Biphasic tumor: larger, polygonal epithelioid cells with large nuclei and dispersed chromatin appear as islands or in an alveolar pattern; these cells contain melanin and are positive for HMB-45, PGP9.5, pancytokeratin, and occasionally S-100 protein; smaller ovoid, poorly differentiated neuroblast-like cells with hyperchromatic nuclei and scant cytoplasm stain for synaptophysin, chromogranin, and CD56; both populations are positive for neuron-specific enolase (Figs. 9-37 and 9-38).
- Increased Ki67 fraction (usually in neuroblast-like cells) and presence of CD99 may correlate with poorer prognosis.
- Metastatic lesions usually contain neuroblast-like cells.

Differential Diagnosis

- Biphasic nature of the tumor and positivity for melanocyte markers rules out other small blue cell tumors of childhood, such as neuroblastoma, rhabdomyosarcoma (myogenin positive and MyoD positive), and Ewing sarcoma/peripheral neuroectodermal tumor (CD99 positive).

Management and Prognosis

- Surgery is treatment of choice; some cases require radiotherapy and/or chemotherapy.
- Recurrence rate is 20%, with more than half of these in the maxilla and occurring within weeks of surgery.

10 Reactive Keratotic Lesions (Nonleukoplakias)

CHAPTER CONTENTS

White Lesions

White lesions are some of the more commonly biopsied lesions and one of the most challenging for general pathologists and dermatopathologists. This is particularly because of confusion over nomenclature (especially over the term *leukoplakia*) and difficulty recognizing oral frictional keratoses, the two most common being morsicatio mucosae oris and benign alveolar ridge keratosis. There are also other frictional/reactive keratoses that are not as well defined histologically. Table 10-1 provides a list of mucosal conditions that are usually white; these are discussed subsequently and in other chapters.

The oral mucosa appears white for several reasons:

- Presence of keratin in a normally nonkeratinized site
- Hyperparakeratosis or hyperorthokeratosis in a normally keratinized site
- Coagulation of superficial keratinocytes
- Edema of keratinocytes
- Alteration of the epithelial cells because of abnormal keratin formation or aggregation (see Chapter 2)
- Dysplasia (see Chapter 11)
- Nonepithelial changes such as underlying scarring and fibrosis

When a mildly irritating substance comes in contact with the mucosa or when there is mild physical surface trauma, superficial cells become edematous and degenerate until the effects of the irritation (contacting chemical or physical irritation) are diluted, beyond which the keratinocytes appear normal. Such changes are seen in leukoedema and morsicatio mucosae oris. Smokeless tobacco lesions in particular show this effect, although over time carcinogens from tobacco may result in significantly keratotic and dysplastic lesions. Aspirin, however, is so caustic that it leads to complete destruction of the epithelial layer, resulting in ulceration and necrosis rather than a keratotic lesion, although the earliest changes may be leukoedema. Irritant contact stomatitis results in a clinical erythematous lesion with spongiosis as its main histologic feature (see Chapter 7). Correlating the histopathologic and clinical findings is key to arriving at an accurate diagnosis.

Reactive Lesions

LEUKOEDEMA

Clinical Findings

- Present in up to 90% of the population; more readily discerned in dark-skinned individuals; history of mild surface injury such as smoking, sucking, or use of strong oral rinses or toothpaste
- Delicate lacy, gray-white lines on the buccal mucosa or tongue (nonkeratinized site) that disappear with stretching (Fig. 10-1)

TABLE 10-1 Histologic Diagnoses for Papulomacular White Lesions

Developmental/Hereditary
Cannon white sponge nevus
Hereditary benign intraepithelial dyskeratosis
Oral pachyonychia congenita

Squamous cell carcinoma
Verrucous carcinoma
Fibrosis (Not Involving the Epithelium)
Submucous fibrosis
Mucosal fibrosis in progressive systemic sclerosis

Etiopathogenesis and Histopathologic Features

Leukodema usually results from mildly irritating fluid substances (cigarette or marijuana smoke or dentifrice) in episodic contact with the mucosa; putative failure of injured cell to maintain sodium pump leads to ingress of water.

- Keratinocyte edema of superficial cells appear pale and ballooned; absent nuclei may be due to plane of section or degeneration; cell membranes have compacted "jigsaw" puzzle appearance; deeper cells show perinuclear halos (but do not represent koilocytes because they lack other nuclear characteristics); usually, minimal-to-no keratin is noted, although keratin chevrons may be present (Figs. 10-2 and 10-3).
- Benign epithelial hyperplasia with minimal-to-no inflammation may be seen.

Differential Diagnosis

- Keratinocyte edema is seen in association with frictional/factitial keratoses.
- Hairy leukoplakia shows nuclear membrane condensations and Cowdry inclusion bodies.
- Koilocytic nuclei have irregular nuclear outlines and hyperchromasia.

Management and Prognosis

- No treatment is necessary for primary leukoedema.

CONTACT DESQUAMATION

Clinical Findings

- Painless, thready white fragments lie on the mucosa (usually nonkeratinized sites) that easily peel off, leaving normal mucosa (Fig. 10-4); surrounding leukoedema may be seen; patients may also develop contact cheilitis.

Etiopathogenesis and Histopathologic Features

Condition results from caustic mouth washes high in alcohol content, strong toothpastes, or other contactants that are irritants but not strong enough to cause necrosis and ulceration.

- Strips of desquamated keratinocytes appear eosinophilic and coagulated (Figs. 10-5 and 10-6).

Management

- Resolution on discontinuation of use of dentifrice

Frictional/Factitial Keratoses

The majority of hyperparakeratotic and hyperorthokeratotic lesions in the oral cavity are reactive, frictional keratoses. Two histologically well-defined frictional keratoses in the oral cavity are morsicatio mucosae oris (generally on the nonkeratinized mucosa) and benign alveolar ridge keratosis (lesions on the keratinized mucosa). The linea alba on the buccal mucosa is considered a variation of normal but is a severe localized leukoedema or a mild morsicatio mucosae oris (Fig. 10-7, *A*)

MORSICATIO MUCOSAE ORIS (MORSICATIO BUCCARUM, PATHOMINIA MUCOSAE ORIS)

Clinical Findings

- Most common locations are close to the biting surfaces of the teeth, namely buccal mucosa, lateral/ventral tongue, and lower labial mucosa (rare on upper labial mucosa); more than 50% of patients are unaware of their habit (which may be nocturnal).
- Poorly demarcated papules and plaques often display a "shaggy," sometimes papillary surface and may be associated with areas of erythema and ulceration, depending on severity of the parafunctional chewing habit (see Fig. 10-7, *B-D*).
- Chronic irritation of the mucosa against an oral appliance or other hard foreign object results in similar findings.

Etiopathogenesis and Histologic Features

Parafunctional habits such as raking of the teeth, prothesis, or other foreign object against the nonkeratinized mucosa results in these benign reactive keratotic lesions.

- Linea alba shows severe leukoedema (Fig. 10-8).
- Classic lesions show marked hyperparakeratosis with fissures and clefts often rimmed by bacteria (impetiginization); superficial keratinocytes exhibit intracellular edema (ballooned and anucleate, see Leukoedema earlier) (Figs. 10-9 and 10-10); the parakeratosis gradually diminishes toward the lateral edges (Fig. 10-11).
- Benign epithelial hyperplasia sometimes with surface papillomatosis is present; rete ridges are tapered; inflammation is usually absent unless ulcer is present; there may be "plasma pooling" (Figs. 10-12 to 10-14).
- Some lesions show only thin hyperparakeratosis and prominent keratinocyte edema (findings noted at the edges of classic lesions); rarely, *Candida* is identified unassociated with inflammation.
- Long-standing lesions may show focal hyperorthokeratosis similar to benign alveolar ridge keratosis (oral lichen simplex chronicus).

It is important that these lesions not be signed out as merely "hyperparakeratosis, acanthosis" because this relegates these lesions to the category of leukoplakia, a nonspecific diagnosis (see Chapter 11).

Differential Diagnosis

- Hairy tongue is characterized by hyperplastic filiform papillae, usually with many bacterial colonies (Fig. 10-15) (see Chapter 1, on normal tongue anatomy).
- Hairy leukoplakia usually shows sharp demarcation of the parakeratin from an underlying pale band of edematous keratinocytes; chromatin beading against the nuclear membrane, Cowdry inclusions, and identification of Epstein-Barr virus (EBV) in the keratinocytes are diagnostic elements.
- Verrucous hyperplasia with hyperparakeratosis usually shows prominent verrucous architecture, and the degrees of dysplasia may be minimal to severe; verrucous carcinoma has an endophytic and pronounced exophytic verrucous configuration and parakeratin clefting with bulbous, frondlike rete ridges.
- Any other papular/nodular lesion, such as a dysplasia or even a fibroma, may show overlying secondary frictional/factitial keratosis.

Management and Prognosis

- Use of barrier devices to prevent patients from habitually chewing the mucosa is not helpful and often leads to raking of the mucosa against the appliance.
- Lesions have no malignant potential and do not require further management.

BENIGN ALVEOLAR RIDGE (FRICTIONAL) KERATOSIS (ORAL LICHEN SIMPLEX CHRONICUS)

Clinical Features

- Poorly demarcated white plaque of the keratinized mucosa of the retromolar pad, gingiva, and palate and particularly where teeth have been extracted (Fig. 10-16); often rough surface

Etiopathogenesis and Histopathologic Features

This is likely caused by trauma of food being crushed against the gingiva or alveolar mucosa from the unopposed teeth and less often by direct impingement of the teeth on mucosa.

- Hyperorthokeratosis with wedge-shaped hypergranulosis and elongated and tapered rete ridges often confluent at the tips; surface of epithelium may have an undulating surface or be significantly papillary; thickness of keratin gradually decreases at the edge of the lesion; inflammation is usually absent (Figs. 10-17 and 10-18).
- Occasionally, hyperparakeratosis may be seen, sometimes with bacterial colonies (Figs. 10-19 and 10-20).

Differential Diagnosis

- Verrucous hyperplasia exhibits papillary or verrucous epithelial hyperplasia with varying degrees of epithelial dysplasia; clinical lesions are usually well demarcated.

Management and Prognosis

- No treatment is necessary, and there is no malignant potential.

NONSPECIFIC BENIGN REACTIVE KERATOSES

Clinical Findings

- White lesion, not well demarcated; present at any site, but often at sites of trauma

Etiopathogenesis and Histopathologic Features

These keratotic lesions do not show the typical histologic features of well-defined keratotic entities, and they may represent waxing or waning specific keratotic diseases, such as lichen planus, healing ulcers, or frictional keratoses such as morsicatio mucosae oris or benign alveolar ridge keratosis.

- Hyperparakertosis or hyperorthokeratosis diminishes at the periphery where it meets normal mucosa; epithelial hyperplasia forms tapered rete ridges; variable chronic inflammation and vascular ectasia; some reactive epithelial atypia is evident; subepithelial fibrin may be present (Figs. 10-21 to 10-24).
- When rendering a diagnosis, the phrase *likely reactive* should be added to *hyperkeratosis, acanthosis,* and *chronic inflammation* because this helps with patient management.

Differential Diagnosis

- Early dysplasia must be ruled out, especially if the clinical lesion is well-demarcated and situated at a high-risk site for dysplasia and oral cancer.

Management and Prognosis

- Removal of possible contact irritants and follow-up with repeat biopsy.
- Excision should be considered if the lesion is well-demarcated and at a high-risk site (if this can be achieved without excessive morbidity).

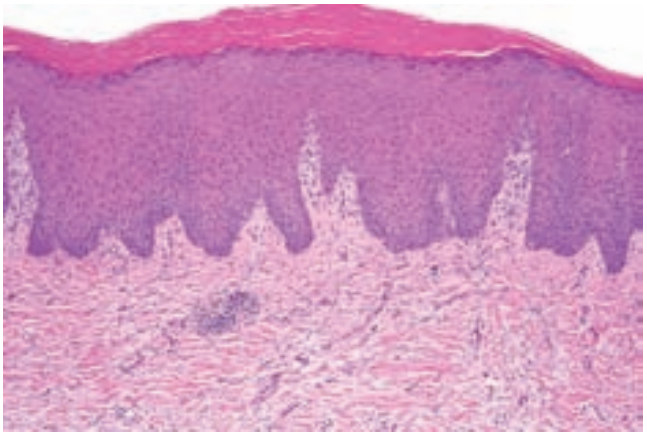

FIGURE 10-21. Likely frictional/reactive keratosis: hyperorthokeratosis, benign epithelial hyperplasia, and mild chronic inflammation, which is likely an early benign alveolar ridge keratosis.

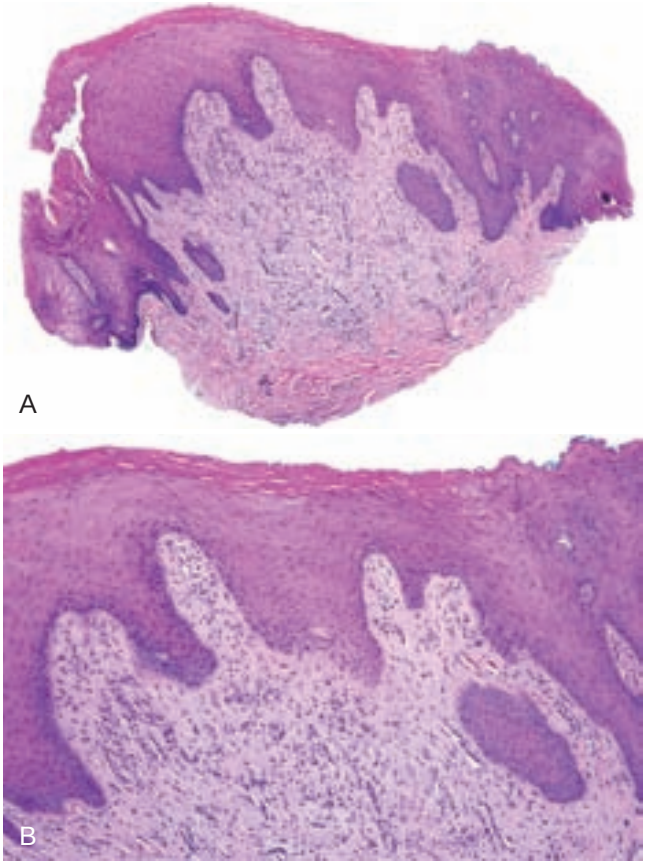

FIGURE 10-22. Reactive keratosis. **A,** Hyperorthokeratosis that diminishes toward the right lateral edge. **B,** Mild focal reactive atypia; this may be the edge of a healing ulcer because of focal squamatization of basal cells and presence of granulation tissue.

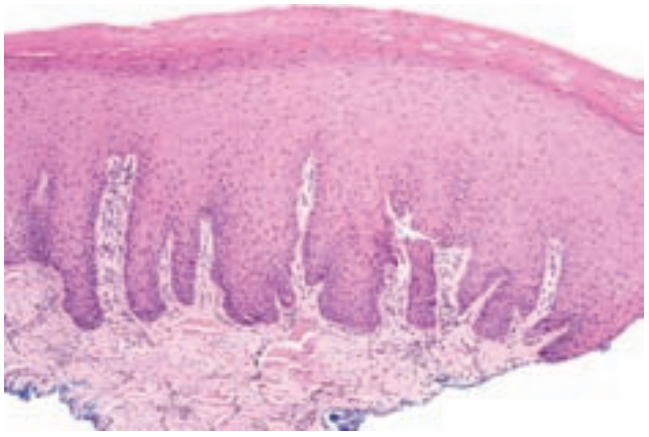

FIGURE 10-24. Likely frictional/reactive keratosis: hyperparakeratosis, epithelial hyperplasia with mild reactive atypia, and mild vascular ectasia.

Tobacco-Related Lesions

SMOKELESS TOBACCO LESION

Smokeless tobacco (either fine snuff or coarser chewing tobacco) has different composition in different countries: in general, moist Swedish snuff ("snus") is lower in tobacco-associated nitrosamines than American moist or dry snuff but has higher alkalinity (pH 8 to 9) and greater tendency to cause mucosal damage. Toombak from Ethiopia has the highest levels of nitrosamines; smokeless tobacco is often mixed with spices and areca nut (gutka or paan) in many Asian countries (see Submucous Fibrosis later). There is interest in using smokeless tobacco in "risk reduction" smoking cessation programs because the risk of oral cancer is much lower when compared with cigarette smoking.

Clinical Findings

- Early lesions are poorly demarcated, uniform gray-white, and edematous with wrinkles and parallel ridges and fissures in the area where the tobacco is placed; teeth may show staining, gingival recession, and root exposure; lesions are usually reversible on stopping the habit (Fig. 10-25).
- More advanced lesions are dense, well-demarcated, keratotic plaques; these areas must be biopsied for evaluation of dysplasia, and the lesions are unlikely to be reversible.

Etiopathogenesis and Histopathologic Features

Smokeless tobacco lesions are caused by contact with caustic agents within the tobacco. Long-standing lesions occur from carcinogens within the tobacco and are essentially lesions of leukoplakia (see Chapter 11).

- Early lesions: slight parakeratosis with prominent keratinocyte edema of superficial cells that stops abruptly; karyopyknosis is common; keratin "chevrons" often are seen, but this is not specific to this condition (see Leukoedema earlier); epithelial hyperplasia is present with minimal reactive atypia and variable chronic inflammation (Figs. 10-26, *A* and *B* and 10-27).
- May see amorphous amyloid-like eosinophilic deposits in the lamina propria and within minor salivary gland parenchyma (see Fig. 10-26, *C*).
- More advanced keratotic lesions exhibit hyperparakeratosis or orthokeratosis with or without dysplasia (see Chapter 11; Fig. 10-28).

Differential Diagnosis

- Other contact lesions may have similar histopathologic features.

Management and Prognosis

- Early lesions generally resolve if the habit is discontinued.
- Hyperkeratotic lesions should be regularly evaluated for dysplasia or excised/ablated with discontinuation of habit.

NICOTINIC STOMATITIS (STOMATITIS NICOTINA)

Clinical Findings

- Symmetric, usually painless involvement of the hard palate, and sometimes the soft palate; mucosa with a white cast (variable in intensity depending on severity of disease) within which are scattered red punctate papules (Fig. 10-29)

Etiopathogenesis and Histopathologic Features

This is a form of reactive keratosis caused by heat (not nicotine) usually from pipe smoking, although it may also occur in heavy cigarette smokers, "reverse smokers" (those who smoke with the lit end of the cigarette in their mouths), and those who frequently drink very hot beverages.

- Hyperorthokeratosis or parakeratosis, benign epithelial hyperplasia, with or without reactive epithelial atypia, and variable chronic inflammation; squamous metaplasia of excretory salivary ducts and chronic sialodochitis (periductal inflammation) (Fig. 10-30).

Management and Prognosis

- Early mucosal changes are generally reversible on stopping the habit.

Submucous Fibrosis

Submucous fibrosis is a premalignant condition seen in areca nut and betel leaf chewers, a practice common in India, parts of South East Asia, and Taiwan. It is included in this chapter because the mucosa appears white, although this is a result of underlying fibrosis rather than significant keratosis.

Clinical Findings

- Diffuse, pale, marblelike but not keratotic areas are on the buccal mucosa, soft palate, and tongue in patients who chew areca nut; late lesions have typical "piano wire" feel to the mucosa from fibrous bands; erythema and ulcers may be present; appearance of leukoplakia or erythroplakia usually precedes development of squamous cell carcinoma (Fig. 10-31, *A*).
- Patients report burning and increasing trismus (see Fig. 10-31, *B*).

Etiopathogenesis and Histopathologic Features

Areca nut contains alkaloids, such as arecoline, that stimulate collagen synthesis and reduce collagen degradation—possibly through the transforming growth factor beta (TGF-β) pathway—and these alkaloids can be converted to carcinogenic nitrosamines. Areca nut contains abundant copper and flavonoids that act together to stabilize and enhance cross-linking of collagen. Areca nut products are part of gutka (which includes slaked lime and powdered tobacco) or paan (which includes slaked lime, spices, and sometimes tobacco wrapped in Piper betel leaf). Gutka use is associated with more rapid development of lesions.

- Hyperkeratosis, epithelial atrophy, and diffuse fibrosis of varying severity are in lamina propria; collagen becomes more dense and more hyalinized with prolonged use (Fig. 10-32).
- Dysplasia often is present in the overlying epithelium in long-standing lesions with subsequent development of invasive squamous cell carcinoma (Fig. 10-33).

Differential Diagnosis

- Fibrosis from trauma is localized with obvious history.
- Progressive systemic sclerosis appears similar, but the presence of autoantibodies and a history of areca nut use differentiates between the two.

Management and Prognosis

- Intralesional injections of corticosteroids, collagenase, hyaluronidase, and systemic treatment with pentoxifylline and interferon-γ have all been useful; surgical excision of the scars with grafting helps to temporarily correct trismus.
- Close follow-up is needed because 7% to 13% of patients develop squamous cell carcinoma.

11 Leukoplakia, Oral Dysplasia, and Squamous Cell Carcinoma

CHAPTER CONTENTS

LEUKOPLAKIA, ERYTHROPLAKIA, AND DYSPLASIA

The term *oral dysplasia* is synonymous with *intraepithelial neoplasia* as used when discussing the cervix. The equivalent terms *squamous intraepithelial neoplasia* and *oral intraepithelial neoplasia* have not to date been universally accepted. The diagnostic term *epithelial atypia* is sometimes used interchangeably with *epithelial dysplasia* and this causes confusion; reactive epithelial atypia should always be reported as such. Diagnosis of dysplasia when there is reactive epithelial atypia may account for why some so-called dysplastic lesions regress over time.

Leukoplakia is not *any* white plaque but rather a white plaque that does not conform clinically or histopathologically to any specific disease and cannot be attributed to reactive, frictional, or traumatic causes. As such, it is a clinical term only and is used when other specific histopathologic and clinical entities are excluded (especially frictional keratoses [see Chapter 10]). Leukoplakia is the most common precursor lesion before invasive cancer develops.

Development of Invasive Carcinoma

- Of all leukoplakias, 9% to 37% (the most recent figure being 47%) represent dysplasia, carcinoma in situ, or invasive carcinoma at time of biopsy.
- Over time, 16% to 36% of dysplasias develop invasive carcinoma.
- Over time, up to 16% of benign hyperkeratosis without dysplasia will develop dysplasia and/or carcinoma.
- The highest incidence of malignancy is on the ventral tongue, floor of mouth, and soft palate, which are all nonkeratinized sites.
- Over time, 60% to 100% of proliferative leukoplakias develop carcinoma.

Clinical Features

- All forms of leukoplakia are more often seen in older individuals. Correlation of histopathologic findings with clinical appearance of lesions is of the utmost importancce in the accurate diagnosis of dysplasia.

Localized Leukoplakia

- *Localized leukoplakia* (at a single site) is more common in men and is strongly associated with smoking; leukoplakia are identified:
  - *Homogeneous leukoplakia* is a uniform white plaque, at least partially well-demarcated, with or without fissuring (Fig. 11-1, *A* and *B*).
  - *Nonhomogeneous leukoplakia* has verrucous/nodular and erythroplakic areas; it has a higher frequency of developing into dysplasia or carcinoma; erythroleukoplakia is more likely to be misdiagnosed clinically as lichen planus because of its red and white character; although typical reticulations are not present and it is unilateral, demarcation is usually best seen around the white/keratotic areas of the lesion (Fig. 11-2; see Fig. 11-1).
- Verrucous hyperplasia of buccal mucosa may be associated with an areca nut habit.

Proliferative Leukoplakia

- Proliferative form is multifocal or extensively affects contiguous sites and often affects gingiva.
- More common in women, it is not strongly associated with smoking; it is present and progressive over 10 to 20 years.
- Homogeneous forms are uncommon; most are nonhomogeneous and usually verrucous/nodular or erythroleukoplakic (Fig. 11-3).

Erythroleukoplakia

- Erythroleukoplakic form is often clinically misdiagnosed as lichen planus because of multifocality and bilaterality; demarcation is usually best seen around the white/keratotic areas of the lesion, which may show fissuring.
- Erythroplakia appears as a velvety red plaque, usually painless; it is much less common than leukoplakia; more than 90% of these lesions are dysplastic or malignant at the time of diagnosis (Fig. 11-4).

Etiopathogenesis and Histopathologic Features

Risk factors for localized leukoplakia (excluding the lip where lesions are usually related to actinic damage) are likely the same as for squamous cell carcinoma: cigarette smoking, excessive alcohol consumption, areca nut habit, history of cancer and cancer therapy, history of prolonged immunosuppression, family history of cancer, and age; risk factors for proliferative leukoplakia are less well-defined. Human papillomavirus (HPV)

TABLE 11-1 Histopathologic Features of Dysplasia

Architectural features	• Bulky and/or endophytic proliferation • Verrucous or papillary epithelial proliferation • Bulbous or drop-shaped rete ridges • Sharply demarcated keratinization, usually multifocal with "skip" areas • Hyperkeratosis with atrophy in the absence of inflammation, usually sharply demarcated
Organizational features	• Loss of stratification and polarity • Dyscohesion • Basal cell hyperplasia • Mitoses (even if normal-appearing) beyond the suprabasal keratinocytes • Keratin pearl formation, usually at tips of rete ridges • Basal cell hyperplasia
Cytologic features (those noted on exfoliative cytology)	• Increased nuclear:cytoplasmic ratio or enlarged nuclei • Variation in nuclear shape (pleomorphism) and size (anisonucleosis) • Variation in cell shape (pleomorphism) and size (anisocytosis) • Coarse chromatin and prominent nucleoli • Abnormal mitoses • Dyskeratosis or keratin pearl formation • Cells with glassy appearance of cytoplasm

is associated with apoptotic dysplasias (see later). Mutations of genes on 3p, 9p, and 17 seen in squamous cell carcinomas have not been consistently found in oral dysplasia.

Architectural Evidence of Dysplasia

Features of dysplasia that occur in the absence of, or with minimal evidence of, cytologic dysplasia are often observed in clinical lesions of verrucous and proliferative leukoplakias (Table 11-1)

- Bulky epithelial proliferation, especially if endophytic and without leukocyte exocytosis or spongiosis (Figs. 11-5 to 11-7); many of these are thick plaques or masses clinically
- Papillary or verrucous epithelial proliferation, broad based, in an exophytic or endophytic configuration, often bulky (Figs. 11-8 to 11-10)
- Bulbous or drop-shaped rete ridges (Fig. 11-11)
- Sharp demarcation of the keratotic area from the adjacent normal epithelium and "skip" areas of normal mucosa sandwiched by hyperkeratotic or dysplastic epithelium (Figs. 11-12 and 11-13)
- Marked hyperorthokeratosis with epithelial atrophy (usually sharply demarcated) in the absence of inflammation and/or not representing a specific disease entity (such as atrophic or treated lichen planus) should be viewed with suspicion; not all dysplasias are hyperplastic lesions
- Sixteen percent of so-called benign hyperkeratoses developing into carcinoma owing to underdiagnosis of these lesions with minimal cytologic atypia.

Organizational Evidence of Dysplasia

Maturation disarray or dysmaturation, and loss of stratification and polarization characterized by basal cell hyperplasia (also cytologic evidence of dysplasia), dyscohesion, increased mitotic activity beyond immediate suprabasilar cells, and keratin pearls within tips of rete ridges may be evident.

Cytologic Evidence of Dysplasia

Cytologic features are similar to those at other mucosal sites and are readily noted on exfoliative cytology (see Table 11-1); reactive epithelial atypia from inflammation may show the same features to a lesser degree.

- Graded mild (less than one third of the thickness of the epithelium involved by dysplasia), moderate (one third to two thirds), and severe (more than two thirds, not including carcinoma in situ) by convention (Figs. 11-14 to 11-16); carcinoma in situ shows full thickness involvement (Fig. 11-17); presence of a lymphocytic band at the interface is common and does not necessarily represent preexisting lichen planus; this is likely a T cell response to altered antigens on dysplastic keratinocytes.
- Involvement of ducts by dysplasia must be documented, because deep margins may not be clear of dysplasia if deep portions of duct are involved; this feature is associated with an increased rate of local recurrence (Figs. 11-18 and 11-19).
- Molecular markers and presence of high-risk HPV is not consistently predictive of subsequent development of invasive carcinoma.

Differential Diagnosis

- Reactive atypia is sometimes difficult to differentiate from true dysplasia, especially in the presence of reepithelialization and healing ulceration; if one cannot be sure, suggest using the phrases *likely reactive, unsure if reactive, unlikely reactive,* or *suspicious for dysplasia* to guide patient management.
- Lichen planus or lichenoid mucositis with reactive atypia tends to show squamatization of basal cells (instead of basal cell hyperplasia) and colloid body formation; multinucleated epithelial cells with finely dispersed chromatin and abundant cytoplasm are often seen in reactive lesions (Fig. 11-20).
- Candidiasis may show significant reactive atypia; to complicate matters, dysplastic epithelium is often colonized by *Candida*, likely because of breakdown of immune surveillance in some cases.

Management and Prognosis

- Multiple biopsies should be performed for nonhomogeneous leukoplakia and proliferative leukoplakia.
- All dysplasias, including mild dysplasias (not reactive atypia) should be carefully followed or excised/ablated, depending on the clinical situation (e.g., high-risk site and high-risk history); recurrence occurs in 30% to 60% of cases.

- Cases that are suspicious for dysplasia because of architectural abnormalities without cytologic evidence of dysplasia, location at high-risk sites, or sharp demarcation may be candidates for narrow excision or ablation, unless morbidity is unacceptable.
- Lifetime follow-up is recommended.

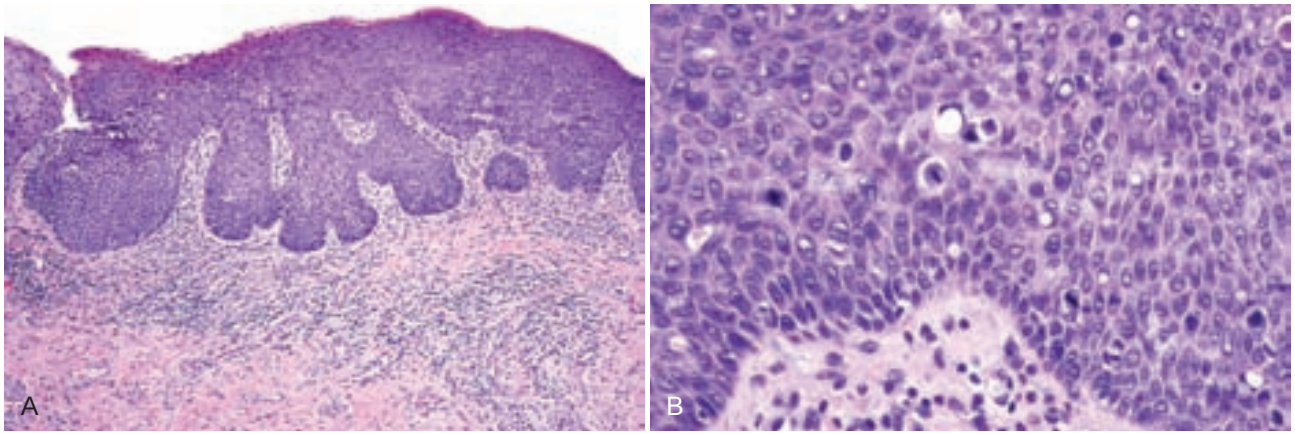

FIGURE 11-17. Carcinoma in situ. **A,** Budding rete ridges, dysplastic cells involving full thickness of epithelium, and lymphocytic infiltrate. **B,** Basal cell hyperplasia, cells with large nuclei, and many high mitotic figures.

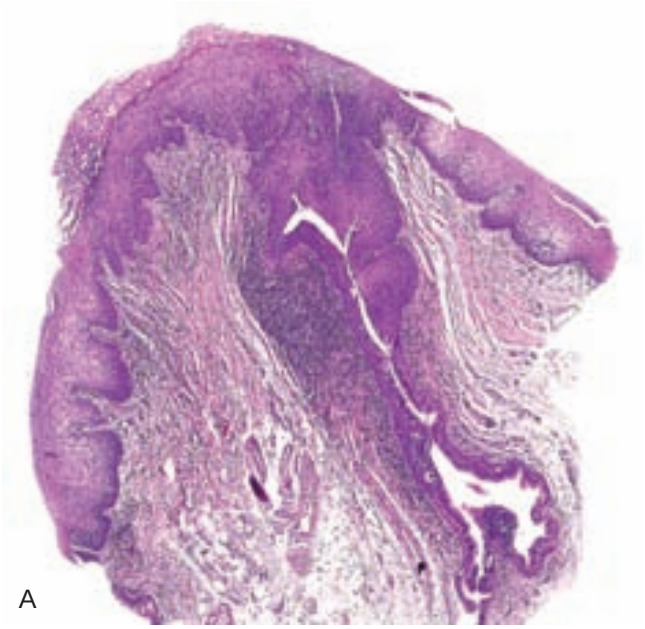

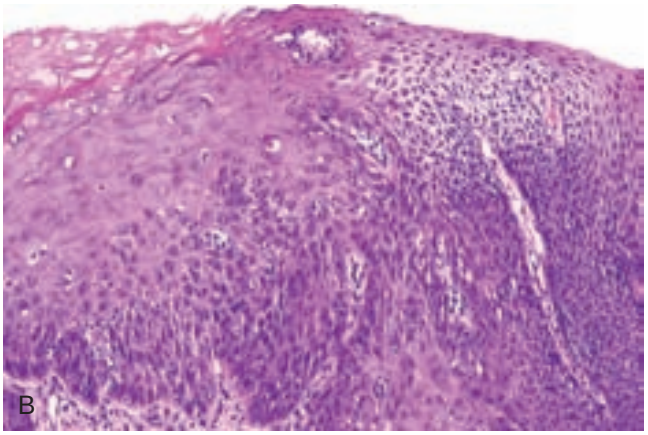

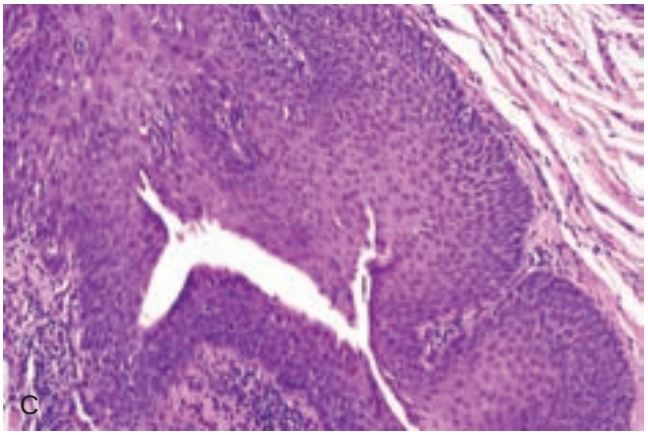

FIGURE 11-18. Moderate-to-severe epithelial dysplasia involving excretory duct. **A,** Sharply demarcated hyperorthokeratosis with dysplasia involving upper portion of duct. **B,** Surface exhibits discohesion, basal cell hyperplasia, and nuclear hyperchromatism. **C,** Dysplasia (basal cell hyperplasia) of duct.

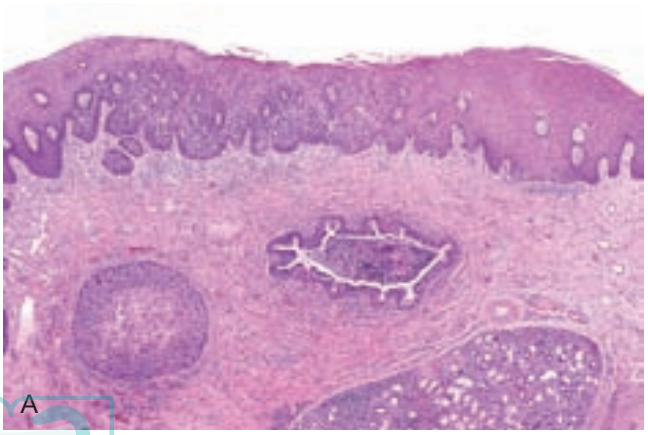

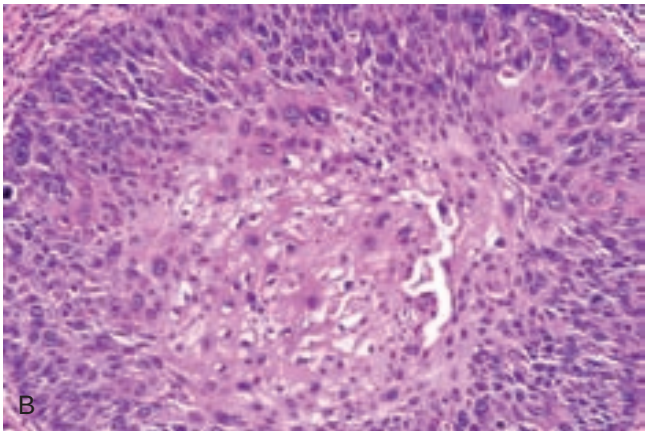

FIGURE 11-19. Moderate-to-severe epithelial dysplasia involving excretory duct. **A,** Overlying epithelium exhibits basal cell hyperplasia; one duct is involved by dysplasia. **B,** Pleomorphic and dysplastic cells involve the full thickness of the duct.

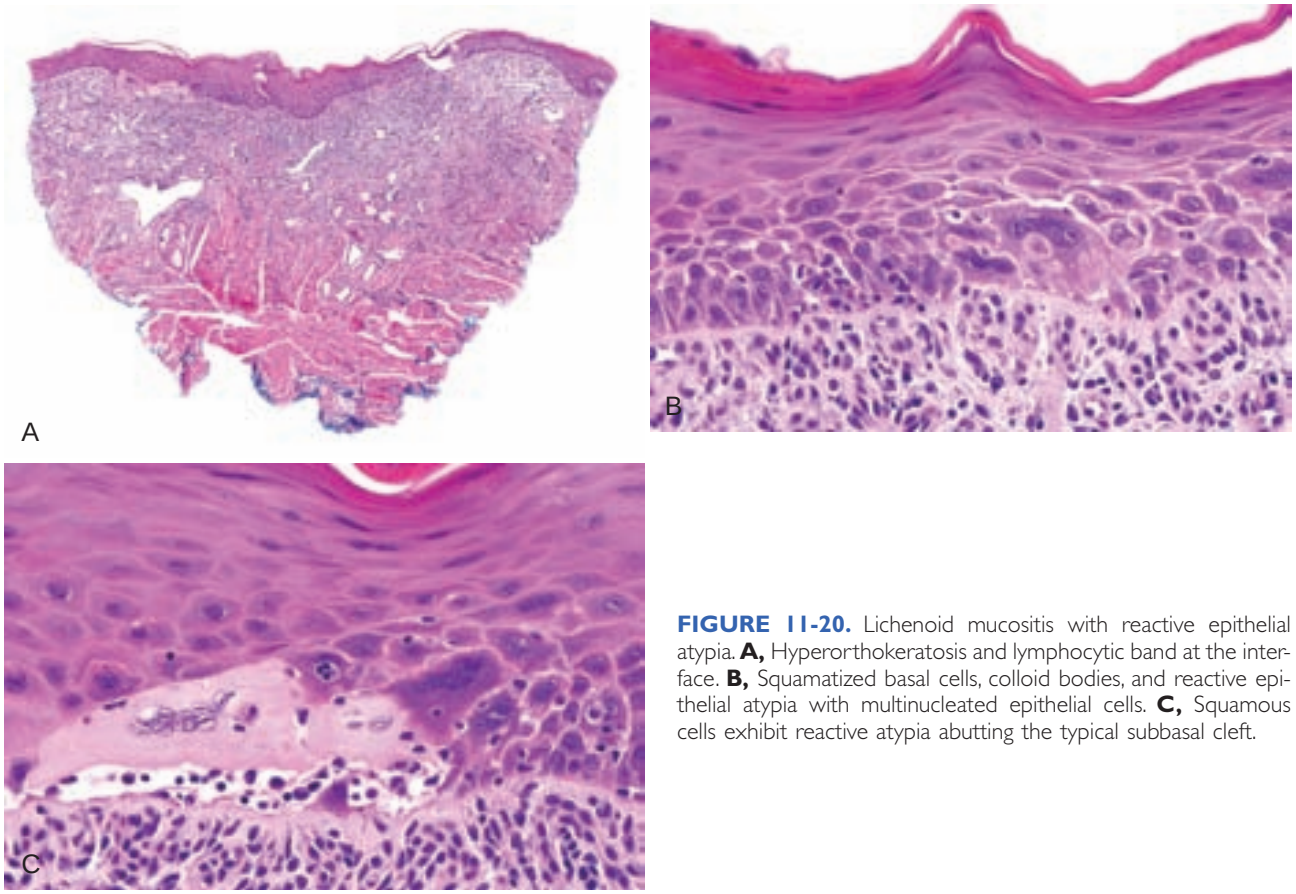

FIGURE 11-20. Lichenoid mucositis with reactive epithelial atypia. **A,** Hyperorthokeratosis and lymphocytic band at the interface. **B,** Squamatized basal cells, colloid bodies, and reactive epithelial atypia with multinucleated epithelial cells. **C,** Squamous cells exhibit reactive atypia abutting the typical subbasal cleft.

HUMAN PAPILLOMAVIRUS–ASSOCIATED APOPTOTIC DYSPLASIA

Clinical Findings

- Indistinguishable from other leukoplakias; sharply demarcated white plaque, usually in adult men

Etiopathogenesis and Histopathologic Features

This condition is associated with high-risk HPV subtypes, and it shares some features with Bowen disease. It has been referred to as koilocytic dysplasia.

- Usually bright parakeratosis; full-thickness involvement by cells in varying stages of apoptosis, from karyorrhexis (similar to mitosoid bodies) to degenerated cells with pyknotic nuclei; apoptotic cells are discohesive with surrounding halos; surrounding keratinocytes exhibit dysplasia, and koilocytes may be present; some cases are papillary (Figs. 11-21, *A-C,* 11-22 and 11-23, *A-C*).
- High-risk HPV subtypes are identified in up to 80% of cases (see Figs. 11-21, *D,* and 11-23, *D*).
- Continuous bandlike p16 positivity is always present (see Fig. 11-21, *E*).

Differential Diagnosis

- Heck disease does not show significant atypia/dysplasia or continuous p16 positivity but will show karyorrhectic cells (mitosoid bodies).
- Conventional carcinoma in situ does not show significant numbers of such apoptotic cells and are p16 and high-risk HPV–negative cells.
- Bowenoid papulosis does not show the same degree of apoptosis.

Management and Prognosis

- Excision with clear margins is treatment of choice.

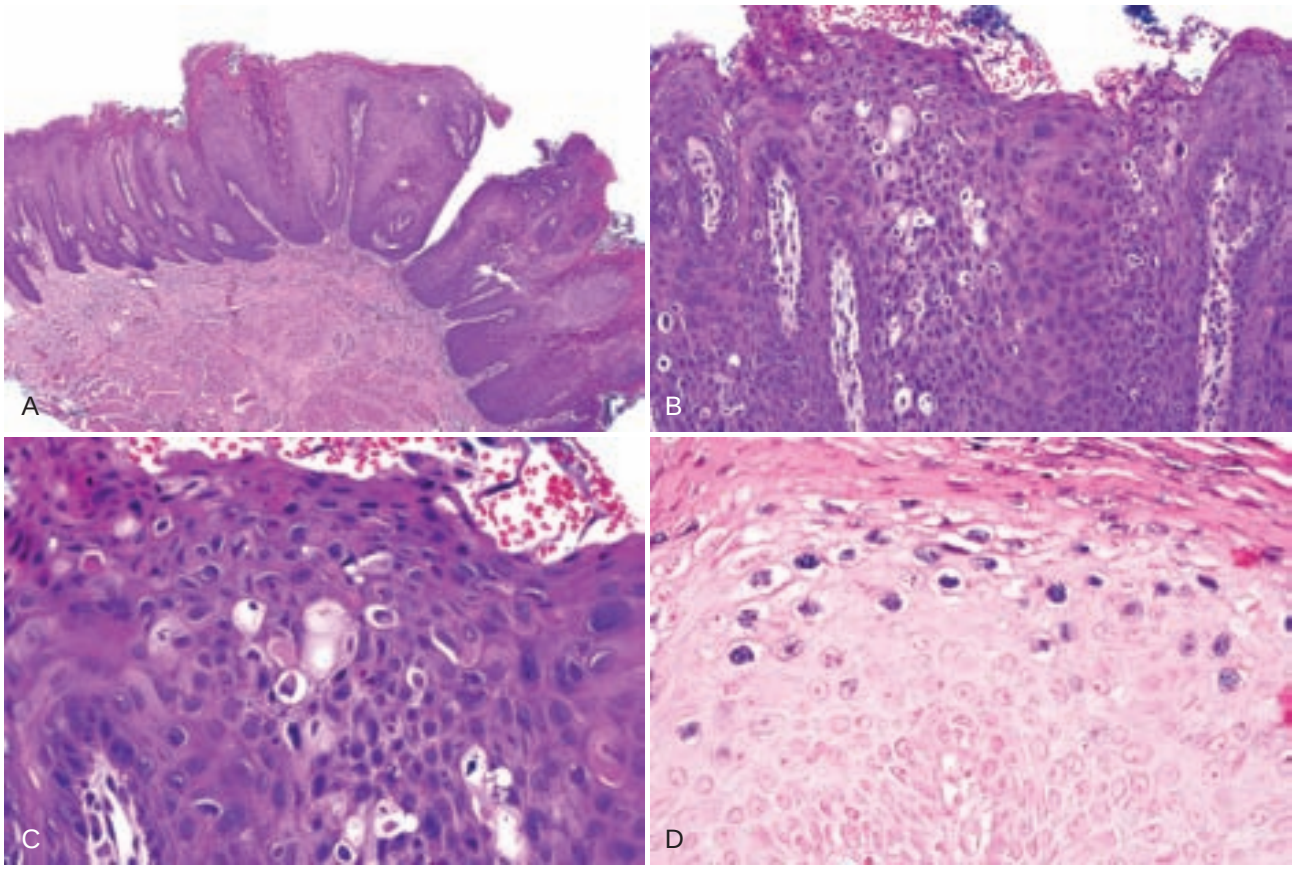

FIGURE 11-23. **A,** Hyperparakeratosis and papillary epithelial hyperplasia. **B,** Apoptotic conventional dysplastic cells are present. **C,** Koilocytes and apoptotic and conventional dysplastic cells. **D,** In situ hybridization is positive for high-risk human papillomavirus subtypes.

SQUAMOUS CELL CARCINOMA

Squamous cell carcinomas are the eleventh most common malignancy in the United States and the sixth most common worldwide. Risk factors are cigarette smoking, excessive alcohol consumption, areca nut habit, history of cancer and cancer therapy, history of prolonged immunosuppression, family history of cancer, and age, similar for oral dysplasia (see earlier), but the most potent are tobacco and alcohol, which have synergistic activity. More recently, HPV infection has been shown to be associated with oropharyngeal and tonsillar carcinomas. Patients with Plummer-Vinson syndrome (iron deficiency anemia, atrophic glossitis,

and esophageal webs) are also predisposed to oral squamous cell carcinoma.

Clinical Features

- Older adults with preexisting leukoplakia, erythroplakia, proliferative leukoplakia, or nonhealing indurated ulcer or mass; may also arise de novo (Fig. 11-24)
- Paresthesia, mobile teeth (if tumor invades the bone), and reduced mobility of soft tissues; only one third are diagnosed with localized tumors

Etiopathogenesis and Histopathologic Features

Benzopyrenes and nitrosamines in cigarette smoke and tobacco products and arecoline in areca nut are carcinogenic agents. Alterations in activity of genes on 3p, 9p and 17 have been consistently found. E6 and E7 oncoproteins of HPV inactivate p53 and Rb tumor suppressor genes, respectively, the latter leading to overexpression of p16, the presence of which is highly correlated with HPV-associated squamous cell carcinoma of the tonsils and oropharynx.

- Several different histologic subtypes exist. Verrucous carcinoma does not tend to metastasize, and oropharyngeal tumors associated with HPV have a better prognosis compared with conventional squamous cell carcinoma. The classification used subsequently is based primarily on morphology and, unless specified, it does not necessarily have prognostic significance.

CONVENTIONAL INFILTRATING SQUAMOUS CELL CARCINOMA

- Malignant epithelial cells proliferate and invade the surrounding stroma as single cells, islands, and cords of epithelial cells; desmoplasia, lymphocytes, and eosinophils are often seen at the tumor front and may or may not correlate with prognosis (Fig. 11-25, *A* and *B*).
- Cytologic changes (See Table 11-1): keratin formation may be abundant (well-differentiated) or the tumor may be minimally to nonkeratinizing; keratin pearl formation may be associated with foreign body reaction (Fig. 11-26; see Fig. 11-25 *C*).
- Overlying and adjacent epithelium exhibits varying degrees of dysplasia, but this may be minimal; candidal infection is common (Fig. 11-27).
- Tumor thickness correlates with recurrence, nodal metastases, and survival, although this is site specific (e.g., tumors ≤ 3 mm exhibit 8% subclinical metastasis, 0% local recurrence, and 100% 5-year survival; tumors ≥ 9 mm show 53% metastasis, 24% recurrence, and 66% 5-year survival).
- Tumors with bulbous rete ridges that infiltrate on a broad front (bluntly invasive) and have significantly lower recurrence and metastases.
- Lymphovascular, perineural, and bone invasion correlate with metastases, local recurrence, and reduced survival.

Management and Prognosis

- Intraoral films, panoramic films, and CT, MRI, and PET scans help delineate extent of tumor.
- Stage I and II tumors are treated with en bloc resection with or without lymph node dissection.
- Stage III and IV tumors are treated with surgery with neck dissection, radiation therapy with or without radiation sensitizers, and/or chemotherapy; cetuximab, a monoclonal antibody against epidermal growth factor receptor has shown promise in improving disease control.
- Sentinel node biopsies are positive in 20% to 30% of clinically benign neck nodes and upstage tumors in 30% to 50% of cases.
- Five-year survival is as follows: 83% with local disease, 55% with locoregional disease, 32% with distant metastases.
- Long-term follow-up is of utmost importance because second primary tumors occur in 7% to 33% of patients.

Squamous cell carcinoma. **A,** Tumor arising in erythroleukoplakia. **B,** Indurated ulcer in floor of mouth with background of faint leukoplakia (anterior). **C,** Mass in buccal mucosa. **D,** Tumor arising in erythroleukoplakia in areca nut chewer (note brown-red staining of teeth). **E,** One-cm indurated mass in floor of mouth had already metastasized to ipsilateral lymph node (stage III).

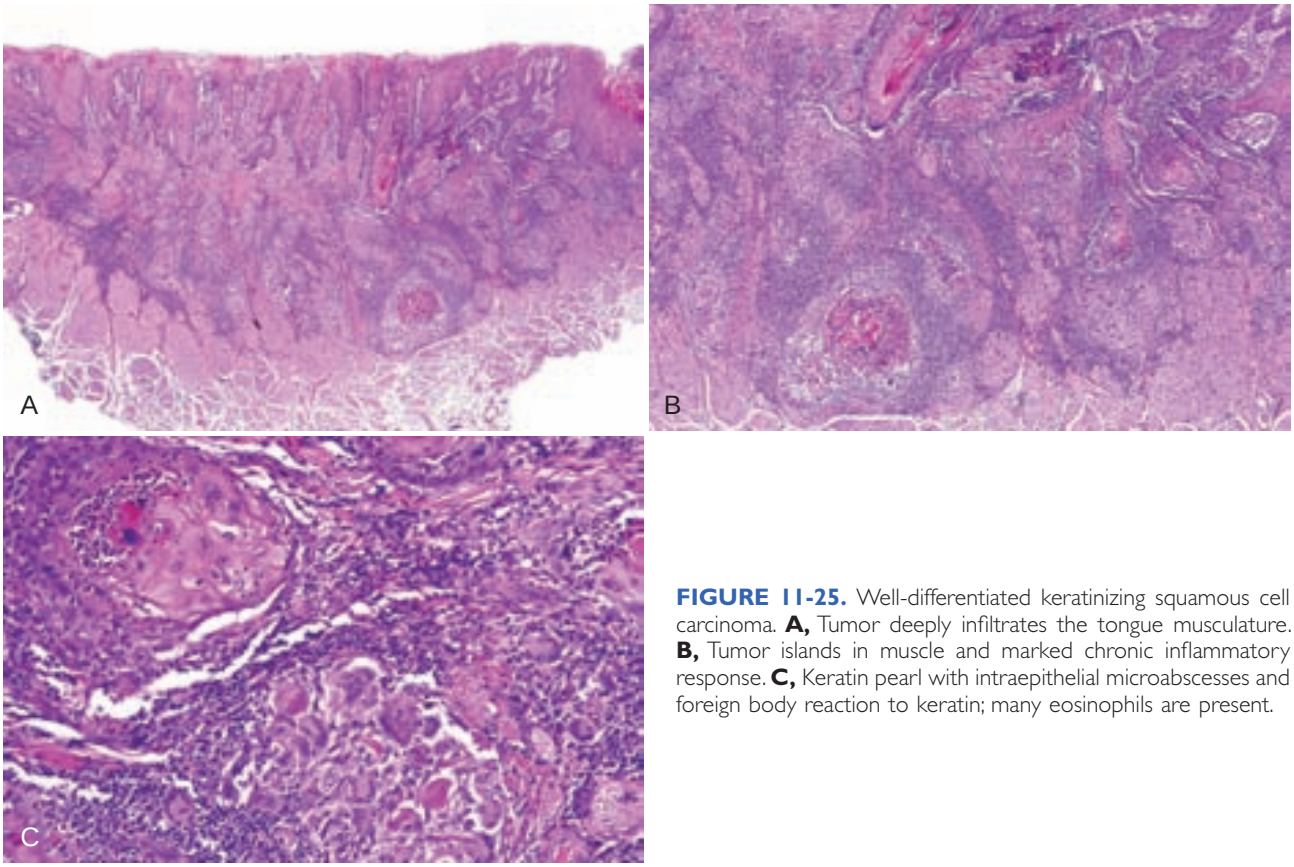

FIGURE 11-25. Well-differentiated keratinizing squamous cell carcinoma. **A,** Tumor deeply infiltrates the tongue musculature. **B,** Tumor islands in muscle and marked chronic inflammatory response. **C,** Keratin pearl with intraepithelial microabscesses and foreign body reaction to keratin; many eosinophils are present.

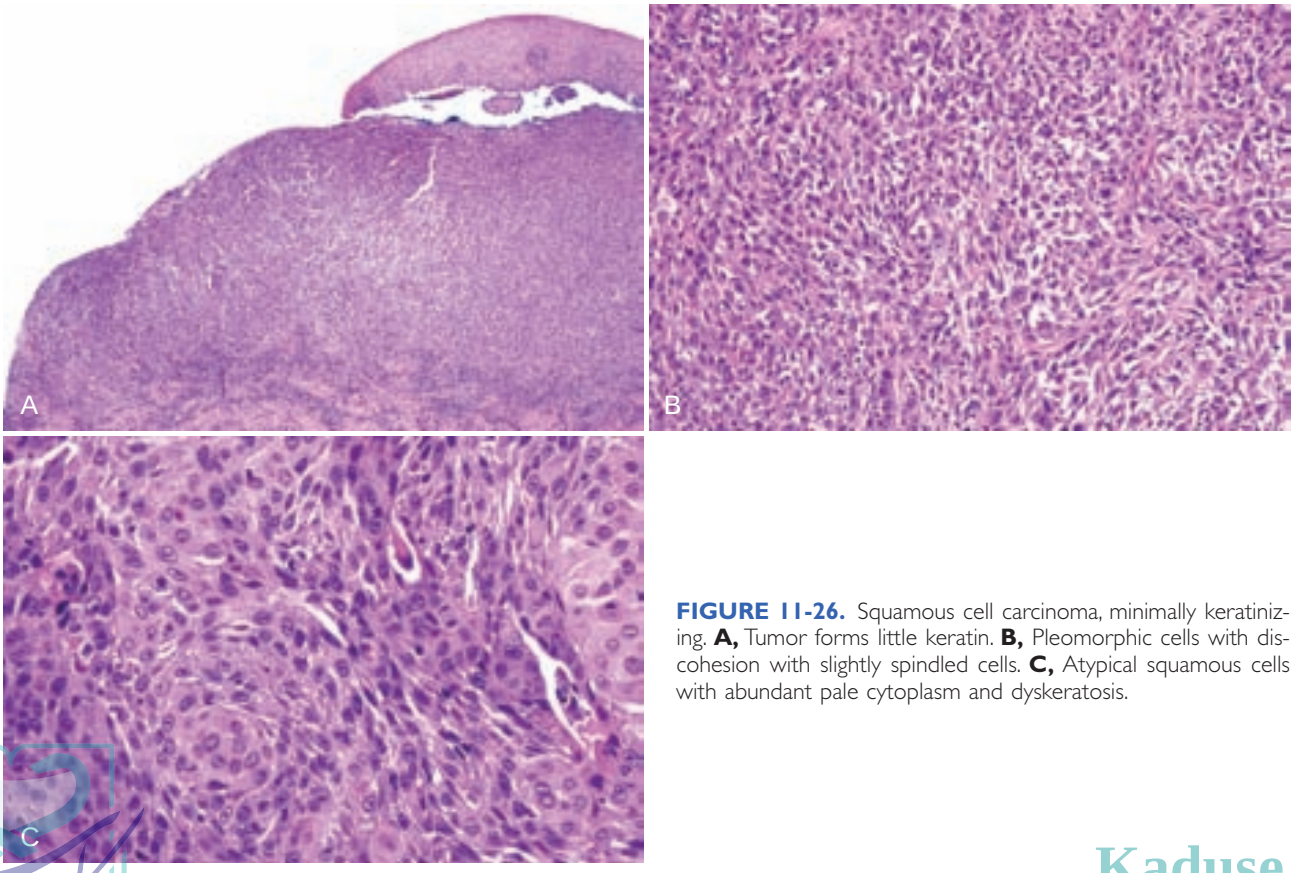

FIGURE 11-26. Squamous cell carcinoma, minimally keratinizing. **A,** Tumor forms little keratin. **B,** Pleomorphic cells with discohesion with slightly spindled cells. **C,** Atypical squamous cells with abundant pale cytoplasm and dyskeratosis.

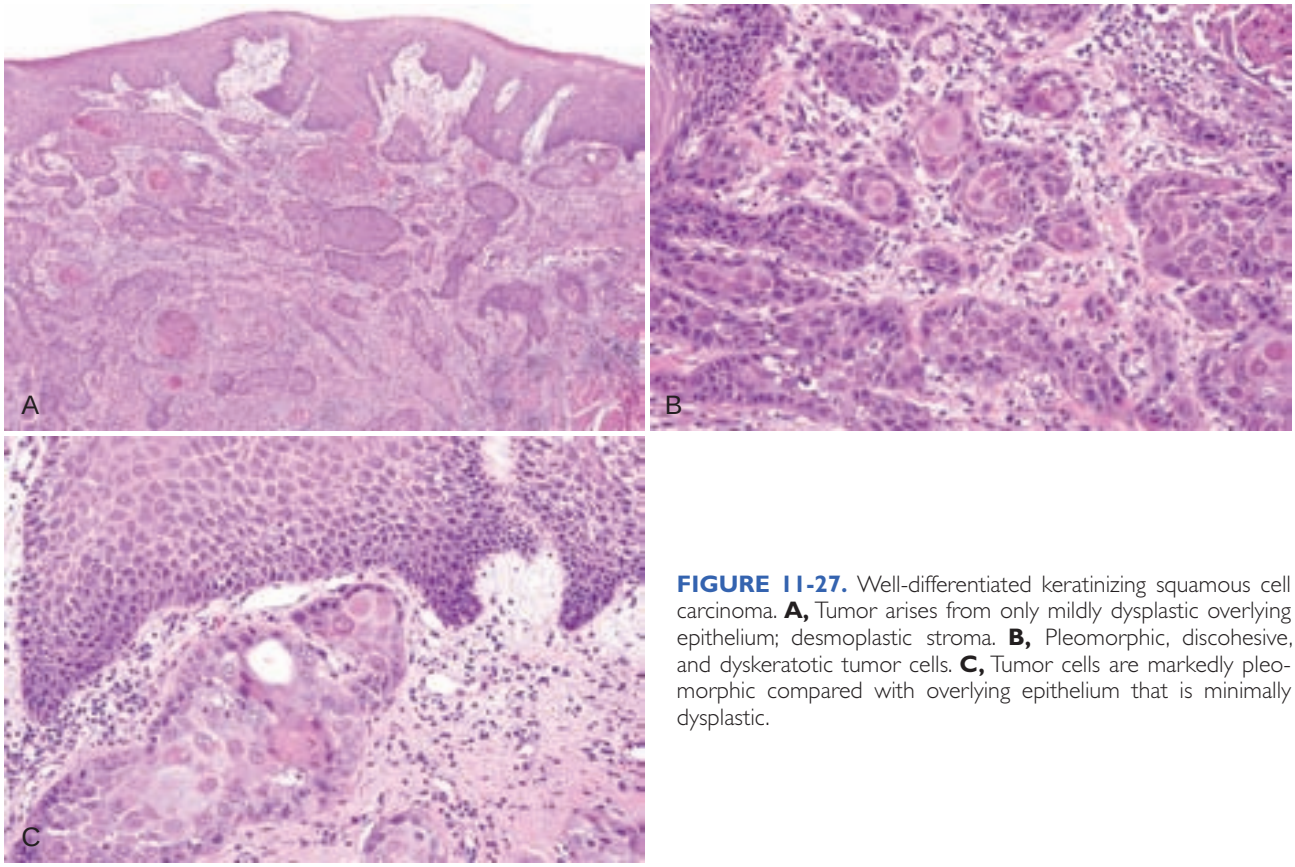

FIGURE 11-27. Well-differentiated keratinizing squamous cell carcinoma. **A,** Tumor arises from only mildly dysplastic overlying epithelium; desmoplastic stroma. **B,** Pleomorphic, discohesive, and dyskeratotic tumor cells. **C,** Tumor cells are markedly pleomorphic compared with overlying epithelium that is minimally dysplastic.

SARCOMATOID SQUAMOUS CELL CARCINOMA

- Lesion usually appears in the posterior oral cavity and is polypoid and ulcerated in nature (Fig. 11-28, *A*); tumor may be associated with history of radiation (see Fig. 11-28, *B*).
- Biphasic cell population; often reveals polypoid proliferation of atypical epithelioid and stellate-shaped cells, as well as spindle cells with a fasciculated or storiform pattern; spindle cells are cytokeratin (especially AE1/3), vimentin, and p63 positive, and S-100, CD10, and calponin negative; pleomorphic cells and mitoses frequently are encountered, and there is overlying epithelial dysplasia; in most cases, conventional keratinizing squamous cell carcinoma is present at the edges of the tumor (Figs. 11-29 to 11-31); rarely, osseous prosoplasia is present.
- Differential diagnoses: nodular fasciitis has feathery or tissue culture myxoid appearance, does not show significant atypia, and spindle cells are cytokeratin negative and SMA positive (Fig. 11-32); desmoplastic melanoma is S-100 positive and may be HMB-45 and Melan-A negative, and cytokeratin negative; spindle cell mesenchymal neoplasms will not have a conventional squamous cell carcinoma with cytokeratin and vimentin-positive cells; myoepithelial carcinomas are positive for S-100 protein and calponin; fibroblasts with radiation-induced atypia do not contain cytokeratin.
- Prognosis: 3-year survival is only 28% in some studies; others show that polypoid lesions have better prognosis compared with deeply infiltrating lesions.

BASALOID SQUAMOUS CELL CARCINOMA

- Usually in the posterior oral cavity; generally discovered at late stage with nodal involvement and poor survival
- Biphasic pattern; proliferation of lobules and sometimes trabeculae of basaloid cells often with comedonecrosis and areas of hyalinization; cells basaloid with hyperchromatic nuclei, scant cytoplasm, indistinct cell borders; many mitoses; should recognize conventional squamous cell carcinoma in lesion (Figs. 11-33 to 11-35); some cases may be positive for high-risk HPV.
- Differential diagnoses: neuroendocrine carcinomas are chromogranin, synaptophysin, and glial fibrillary acidic protein (GFAP) positive, and they would not contain conventional squamous cell carcinoma; HPV-associated oropharyngeal nonkeratinizing squamous cell carcinoma—a distinct subtype of head and neck carcinoma that has basaloid morphology (discussed subsequently)
- Prognosis: 3-year survival approximately 35%

HUMAN PAPILLOMAVIRUS–ASSOCIATED OROPHARYNGEAL AND TONSILLAR NONKERATINIZING SQUAMOUS CELL CARCINOMA

- Patients are 5 to 10 years younger, and disease is mostly in the oropharynx; not strongly associated with smoking.
- Cells are ovoid with indistinct cytoplasmic outlines, moderate amounts of pale cytoplasm, and ovoid nuclei with small nucleoli and dispersed chromatin; they are positive for HPV-16 (most common), -18, -31, -33 or -35, p16, and epidermal growth factor receptors (Figs. 11-36 to 11-38).
- Nodal metastases are usually present; conversely, carcinomas (often cystic) that are p16 positive within cervical nodes usually represent metastases from occult primary tumors in the oropharynx or tonsil.
- Differential diagnosis: basaloid squamous cell carcinoma has conventional squamous cell carcinoma; however, some HPV-associated carcinomas may be keratinizing, and some baslaoid squamous cell carcinomas may be HPV and p16 positive.
- Prognosis: 3-year survival is significantly better than for conventional squamous cell carcinoma (82% vs. 57%); prognosis may also be improved if tumor is p16 positive regardless of HPV status.

ADENOID SQUAMOUS CELL CARCINOMA

- Usually on the lower lip; male predominance
- Biphasic pattern; proliferation of malignant squamous epithelium with acantholysis (usually marked) and/or formation of pseudoglandular structures (Fig. 11-39); should recognize conventional keratinizing squamous cell carcinoma (Fig. 11-40); subtle acantholysis may suggest vascular lumen formation
- Differential diagnoses: adenocarcinomas of salivary gland or skin adnexal origin if conventional squamous cell carcinoma not present; true acantholytic lesions, such as focal acantholytic dyskeratosis, display dyskeratotic cells without cytologic atypia and are not invasive, although these must be distinguished from acantholytic carcinoma in situ; angiosarcomas are CD31 positive
- Prognosis: more aggressive behavior in the oral cavity than on sun-exposed skin

ADENOSQUAMOUS CELL CARCINOMA

- Occurs most commonly in the posterior oral cavity in males, after which the larynx, floor of mouth, and tongue are common intraoral sites.
- Biphasic pattern; proliferation of malignant squamous and basaloid epithelial cells with the formation of ductlike structures containing mucous cells; often carcino-embryonic antigen (CEA), CAM 5.2, and CK7 positive); adenocarcinoma in situ or otherwise and conventional squamous cell carcinoma seen with overlying dysplasia (Figs. 11-41 and 11-42); perineural invasion is seen in some cases; 16% associated with high-risk HPV and p16 positivity.
- Differential diagnoses: mucoepidermoid carcinoma shows less cytologic atypia (except for high-grade lesions) and keratinizing squamous cell carcinoma is not identified.
- Prognosis is poor, with 45% exhibiting local recurrence, 65% with nodal metastases, and 40% to 50% dying of disease within 2 years.

VERRUCOUS CARCINOMA

- Lesions are often seen on the alveolar ridge, mandibular sulcus, or buccal mucosa in patients who use smokeless tobacco.
- Papillary exophytic and endophytic proliferation of squamous epithelium with marked parakeratosis and bulbous frondlike rete ridges with parakeratin plugging.
- Bulbous, frondlike rete ridges with smooth, rounded outlines are bluntly invasive, pushing into the stroma on a broad advancing front without single cell infiltration; minimal cytologic atypia; a lymphocytic band and subbasal clefting may be seen at the interface (Figs. 11-43 and 11-44).
- HPV can be seen in some cases, but p16 studies are lacking.
- Differential diagnoses: bluntly invasive papillary well-differentiated squamous cell carcinoma shows significant epithelial atypia, often with keratin pearls and microabscesses at the tips of rete ridges; serial sectioning is advisable to identify areas of single cell stromal infiltration and microinvasion (Fig. 11-45); condyloma acuminatum may appear similar, especially if irritated and inflamed; cases of so-called hybrid verrucous carcinoma is likely a well-differentiated papillary squamous cell carcinoma.
- Prognosis: surgery is the treatment of choice; radiation therapy is controversial with reports of anaplastic transformation in some cases; correct diagnosis is key to appropriate therapy.

Verrucous carcinoma. **A,** Exophytic and endophytic papillary proliferation of epithelium with parakeratin plugging and bulbous rete ridges; cells have pale cytoplasm. **B,** Broad frondlike rete ridges with subepithelial cleft. **C,** Minimal cytologic atypia; cells have pale, glassy cytoplasm.

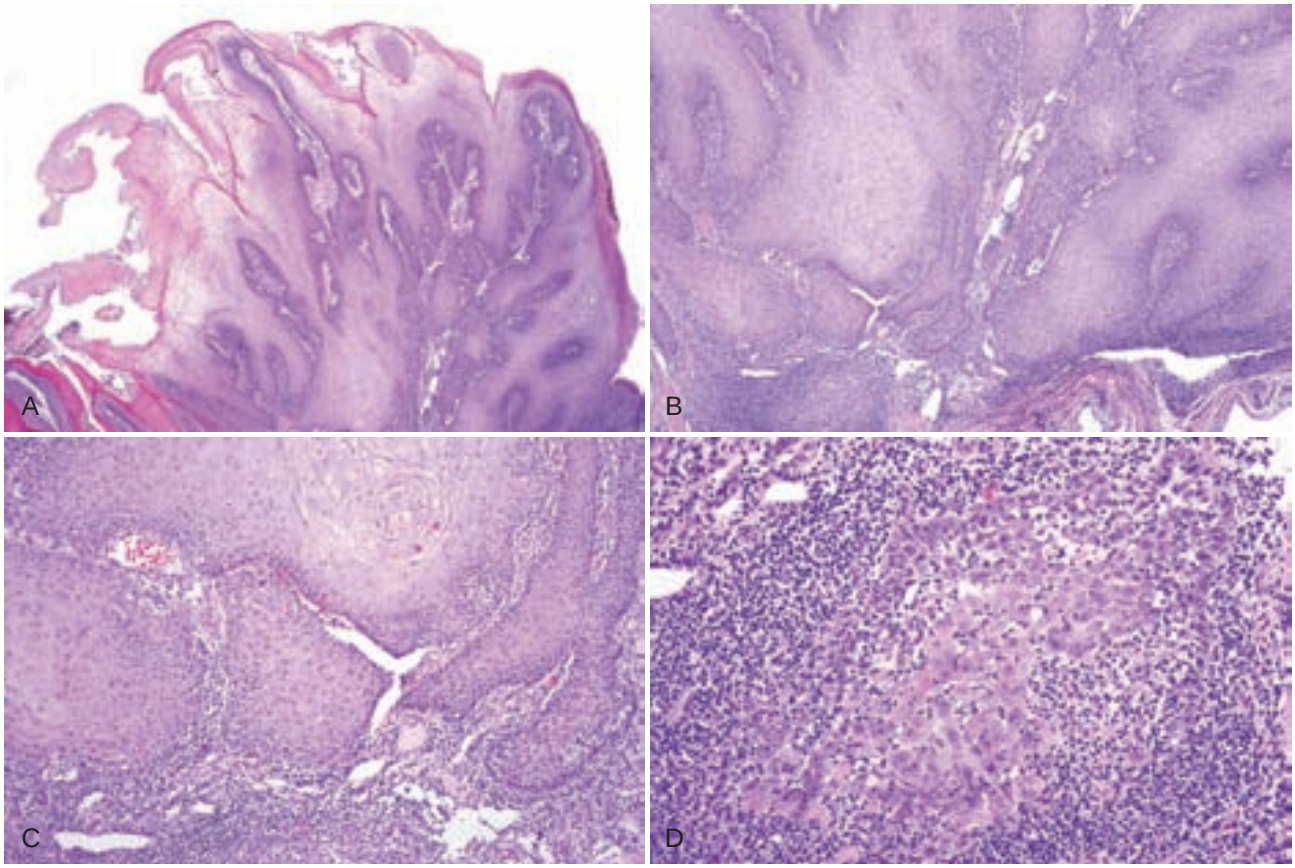

FIGURE 11-45. Well-differentiated papillary squamous cell carcinoma. **A,** Low-power view bears resemblance to verrucous carcinoma with hyperparakeratosis, bulbous rete ridges, and endophytic proliferation of pale epithelial cells. **B,** Moderate atypia and blunt infiltration of stroma with rounded, smooth, rete ridges in some areas; anastomosing complex architecture present. **C,** Base of rete ridges shows dyskeratosis; minimal cytologic atypia. **D,** One focus of highly atypical cells represents early microinvasive squamous cell carcinoma.

PAPILLARY SQUAMOUS CELL CARCINOMA

- Papillary exophytic and endophytic proliferation of squamous epithelium that, unlike verrucous carcinoma, may show paraorthokeratosis or orthokeratosis, significant epithelial atypia, and often microabscesses at tips of bulbous rete ridges; tumor may be bluntly invasive or may invade as single cells or small islands of tumor cells (Figs. 11-46 and 11-47).
- A variant more common in the oropharynx resembles a sessile squamous papilloma with dysplasia; complex arborizing pattern and minimal-to-no surface keratin; blunt invasion rather than single cell infiltration of stroma is frequent; high-risk HPV and p16 has been identified in the majority of cases (Fig. 11-48; see Fig. 11-38, *A-C*).
- Differential diagnoses: well-differentiated squamous cell carcinoma with a keratoacanthomatous pattern (previously called keratoacanthoma) has a cup-shaped morphology with a central crater filled with keratin; cells have glassy cytoplasm, and infiltration of stroma may be similar to conventional squamous cell carcinoma or may be blunt (Fig. 11-49); this keratoacanthomatous pattern has been reported in carcinomas in children; pseudoepitheliomatous hyperplasia in reaction to candidiasis does not show the complex arborizing architecture and does not exhibit significant cytologic atypia.
- Prognosis: 44% of patients die of disease within 2 years; laryngeal tumors have a better prognosis than those at other sites.

CUNICULATE CARCINOMA (CARCINOMA CUNICULATUM)

- Lesions are most commonly reported on the plantar surface of the foot, and skin lesions are considered a variant of verrucous carcinoma.
- Lesion occurs on the gingiva/alveolar ridge and majority show direct intraosseous extension.
- Lesion is a rare variant of squamous cell carcinoma with thin trabecular and ribbon-like proliferation of squamous epithelium with complex arborizing morphology and convoluted irregular keratin-filled cysts to the extent that connection with the surface epithelium may be difficult to identify; variable cytologic atypia (Fig. 11-50).
- Differential diagnosis: verrucous carcinoma is less likely, because the epithelium lining cystlike structures is thin and shows significant atypia; some squamous cell carcinomas may form one or two cystic structures that are not tortuous (Fig. 11-51).
- Prognosis: some tumors behave indolently and do not metastasize, although this may depend on the degree and nature of stromal infiltration.

12 Inflammatory Salivary Gland Disorders

CHAPTER CONTENTS

MUCOCELE

Mucoceles in the oral cavity are cystlike collections of salivary mucin that spills out of a traumatized duct.

Clinical Findings

- Mucoceles are most common in the first 3 decades of life.
- Dome-shaped, bluish, sessile nodules, mucoceles are commonly located on the lower labial mucosa (70% to 90%), ventral tongue (ranula), buccal mucosa, and floor of mouth; they wax and wane and are usually painless (Fig. 12-1, *A-C*); 44% of mucoceles resolve spontaneously.
- Superficial mucoceles are seen in patients with hyposalivation; they are most frequent on the palate (such as in patients with chronic graft-versus-host disease) and resemble painless blisters or vesicles, often leading to a clinical misdiagnosis of herpes infection (see Fig. 12-1, *D*); the latter are almost always extremely painful.

Etiopathogenesis and Histopathologic Features

Mucoceles are pseudocysts that arise from trauma to the excretory salivary duct; this leads to escape of mucous into the surrounding soft tissues, which become walled off by granulation tissue and eventually organized by fibrous tissue.

- Cystlike cavity fills with mucin with variable numbers of neutrophils, muciphages, and, sometimes, eosinophilic spherules surrounded by condensed granulation tissue containing muciphages; these globules are mucicarmine positive and may represent mucin condensations; a feeder duct exhibiting squamous metaplasia may be seen; mucin may be inconspicuous within the wall (Figs. 12-2 and 12-3).
- Mucin may be present diffusely in the connective tissue (Fig. 12-4); lesions not removed intact manifest as fragments of granulation tissue with muciphages (Fig. 12-5); ventral tongue lesions tend not to have a thick wall of granulation tissue (Fig. 12-6).
- Minor salivary glands exhibit variable degrees of obstructive changes, namely acinar atrophy, ductal dilatation with inspissated secretions, periductal hyalinization, interstitial fibrosis, and interstitial lymphoplasmacytic infiltrate (Fig. 12-7).
- Organizing mucoceles consist of a solid mass of granulation tissue with muciphages; mucin generally is inconspicuous, and a mucin pool is absent (Fig. 12-8); muciphages may sometimes have clear cytoplasm (Fig. 12-9).
- Superficial mucoceles contain mucin pools that abut the overlying atrophic epithelium; a collarette of epithelium forms part of the wall of the mucocele (Figs. 12-10 and 12-11).
- Papillary synovium–like areas are sometimes seen (Fig. 12-12).

Differential Diagnosis

- An organizing mucocele with a predominance of clear cells may resemble salivary gland neoplasm such as mucoepidermoid carcinoma or even clear cell carcinoma, but there is lack of stromal invasion by nests of neoplastic cells.
- Obstructive changes are often diffuse and should not be confused with autoimmune sialadenitis seen in Sjögren syndrome, in which obstructive changes are minimal and the lymphocytic infiltrate is strikingly periductal, at least in early stages (see later); focal periductal lymphocytic infiltrates are not uncommon in obstructive sialadenitis.

Management

- Enucleation or excision of mucoceles, sometimes with overlying mucosa (especially superficial mucoceles), and excision of salivary glands in the vicinity, down to muscle
- May recur (rate of up to 8%) from further damage of salivary glands

SALIVARY DUCT CYST (SALIVARY RETENTION CYST, SIALOCYST)

Clinical Findings

- Tends to occur in the maxillary and mandibular sulcus/vestibule (mucobuccal fold) and upper lip (where it is often associated with sialoliths) in adults
- Appears as bluish nodule that may feel hard if a sialolith is present

Etiopathogenesis and Histopathologic Features

These true cysts arise from retention of secretions within a duct from a distal obstruction, or from presence of a sialolith.

- These cysts consist of cystically dilated excretory salivary duct that may be lined by a double layer of low cuboidal-to-columnar cells or may exhibit metaplastic change—squamous, ciliated cell, or oncocytic (oncocytic sialocyst); it may have slight papillary projections in the lining (Figs. 12-13 to 12-15); a sialolith may be present; variable lymphoplasmacytic infiltrate present.
- Oncocytic sialocystosis (papillary or otherwise) shows multiple cystic structures in both extralobular and intralobular locations; surrounding minor glands exhibit obstructive changes (see Mucocele) (Figs. 12-16 and 12-17); should not be overdiagnosed as papillary cystadenoma.

Differential Diagnosis

- Multifocality and lack of encapsulation or significant adenomatous component differentiates sialocystosis from cystadenoma, although distinction may be difficult (see Chapter 13).
- Gingival cyst of the adult is often mistaken for salivary duct cyst, but the latter does not occur on the attached gingiva, which has no salivary glands.

Management

- Enucleation or excision with surrounding glands is curative.

SIALOLITH (SALIVARY CALCULUS)

Clinical Findings

- Firm-to-hard nodule, usually asymptomatic (unless ruptured and inflamed), often in the upper lip in minor glands.
- Most common site in the major glands is the floor of mouth within Wharton (submandibular) duct, causing pain from pressure just before meals ("meal symptoms"); may be seen on intraoral occlusal radiographs if it is sufficiently calcified (Fig. 12-18).

Etiopathogenesis and Histopathologic Features

Sialoliths form from a central nidus of cellular debris, bacteria, or mucous plugs and are unassociated with hypercalcemic syndromes. They are more common in

the Wharton duct because of the length of the duct, its tortuous course, and the relatively thick mucinous secretions.

- Basophilic concentric lamellar and globular calcifications occur within a cystically dilated duct that exhibits squamous and often mucous cell metaplasia; suppuration may be seen if there is infection (Figs. 12-19 to 12-21); associated minor glands exhibit obstructive changes.
- Bacteria may be identified in rare cases (Fig. 12-22).

Differential Diagnosis

- Phleboliths are usually smaller; they do not have a globular component, and they are present within venules.

Management

- Excision of the minor salivary glands with the sialolith is curative.
- Excision of the submandibular sialolith with exteriorization of the duct is curative; lithotripsy is also effective.

CHEILITIS GLANDULARIS (STOMATITIS GLANDULARIS, CHEILITIS GLANDULARIS APOSTEMATOSA)

Clinical Findings

- Seen in older adults, usually males
- Asymmetric, often painful swelling or nodule, usually on the lower lip that typically becomes everted; usually concurrent actinic damage to lips (Fig. 12-23); simple, deep, and deep suppurative forms recognized

Etiopathogenesis and Histopathologic Features

Chronic inflammation and suppuration involve the salivary ducts; etiology is unknown, although actinic damage may play a role.

- Cystically dilated excretory ducts show periductal acute and chronic inflammation and luminal suppuration (Fig. 12-24).
- Overlying mucosa may show dysplasia and/or invasive carcinoma.

Differential Diagnosis

- Presence of a sialolith, ruptured salivary duct cyst, or trauma may produce similar changes.

Management

- Antibiotics are used for infection if pain and/or suppuration is present.
- Excision of lesion is curative; dysplasia in the epithelium must be treated appropriately.

NECROTIZING SIALOMETAPLASIA

Clinical Findings

- Lesion is more common in males (3:1 male predominance) and usually occurs on the hard palate.
- Lesion starts as a swelling that breaks down over a few days to weeks to form necrotic and ulcerated tissue that sloughs; it may or may not be painful (Fig. 12-25).
- Patient may have history of a greater palatine anesthetic block; reported in patients with Raynaud disease, Buerger disease, and bulimia; rare cases are associated with an adjacent malignancy.

Etiopathogenesis and Histopathologic Features

This condition is caused by ischemia and infarction of the glands.

- Preservation of the lobular architecture of the glands is an important finding that is not always present (Fig. 12-26, *A*)
- Early stage—spillage of mucin into the interstitium of the gland parenchyma; ghostly outlines of the acini with preserved basement membrane but erased acinar cell outlines (Fig. 12-27; see Fig. 12-26, *B*) are classic features.
- Late stage—squamous metaplasia of the ducts may be marked but without significant pleomorphism or abnormal mitoses (see Fig. 12-26, *C*).
- There is variable acute and chronic inflammation, necrosis, and secondary thrombiosis.

Differential Diagnosis

- Lack of significant cytologic atypia and abnormal mitoses rules out a squamous cell carcinoma.

- Subacute necrotizing sialadenitis shows marked mixed inflammation with focal necrosis.

Management

- Lesion resolves on its own without medical or surgical intervention by spontaneous exfoliation of the necrotic tissue; intralesional steroid therapy may be helpful.

SUBACUTE NECROTIZING SIALADENITIS

Clinical Findings

- Lesions are diffuse, erythematous, usually nonulcerated, painful swellings of the hard palate (majority of cases), soft palate, tonsil, and (less commonly) buccal mucosa, tongue, and lip; usually occurs in young adults in the second and third decades.

Etiopathogenesis and Histopathologic Features

The etiology is unknown, but infectious and hypersensitivity theories have been put forward. Some believe that this is a variant of necrotizing sialometaplasia, although this is unlikely.

- Diffuse interstitial infiltration by neutrophils, lymphocytes, plasma cells, histiocytes, and, often, eosinophils; possible inflammation of surrounding muscles

and nerves; maintenance of lobular architecture (Fig. 12-28, *A* and *B*)

- Multifocal acinar atrophy and necrosis secondary to inflammation; ductal dilatation with flattened ductal epithelium, loss of ductal integrity, and spillage of mucin (see Fig. 12-28, *C*)

Differential Diagnosis

- Necrotizing sialometaplasia is usually ulcerated but painless; it occurs in older patients, has a longer onset of many days to a few weeks, and is a more extensive lobular ischemic necrosis.
- Chronic sclerosing sialadenitis (Kuttner tumor) is seen mainly in the submandibular gland and is characterized by preservation of lobular architectures, florid lymphoid hyperplasia with geographic germinal centers, hypercelluar interlobular fibrosis, acinar atrophy, and abundant IgG4 plasma cells; current thinking suggests that this represents IgG4-related sclerosing disease.

Management

- Self-limited and heals within a few weeks of the biopsy

AUTOIMMUNE SIALADENITIS

Primary Sjögren syndrome involves the salivary and other exocrine glands, whereas secondary Sjögren syndrome exhibits concurrent involvement of other organ systems (such as with lupus erythematosus and rheumatoid arthritis).

Clinical Features

- More than 80% are female, middle aged and older
- Dry eyes and dry mouth (keratoconjunctivitis sicca) and dry nasal passages
- Elevated antinuclear antibody, rheumatoid factor, and Ro and La antibodies; serum protein electrophoresis studies abnormal

Etiopathogenesis and Histopathologic Features

Sjögren syndrome is an autoimmune disease characterized by T cell destruction of the exocrine glands and, in particular, the salivary glands.

- *Minor salivary glands:* periductal collections of 50 or more lymphocytes within a 1 mm^2 area called foci (Fig. 12-29); the higher the focus score, the more likely the diagnosis of Sjögren syndrome; as disease progresses, the lymphoid infiltrate replaces much of the gland parenchyma; lobular architecture is maintained; there is minimal evidence of nonspecific obstructive changes, such as significant ductal dilatation and interstitial fibrosis.
- If lymphocytes spill out of the lobules, forming a diffuse infiltrate with effacement of lobular architecture, work-up for lymphoma is indicated.
- *Major salivary gland:* lymphoepithelial sialadenitis is composed of islands and strands of epithelial cells in a diffuse lymphocytic infiltrate; lobular architecture is maintained; effacement of lobular architecture and proliferation of monocytoid lymphoid cells around lymphoepithelial islands usually indicate presence of evolving lymphoma (usually marginal zone B-cell–type) (Figs. 12-30 and 12-31)
- Light chain restriction within plasma cells and heavy chain gene rearrangements are associated with progression to lymphoma.

Differential Diagnosis

- Similar minor gland changes are seen in other connective tissue diseases.
- Lymphocytes in a periductal and interstitial location with prominent ductal ectasia and acinar atrophy are nonspecific findings or are caused by obstruction (Fig. 12-32).

Management

- Reduce discomfort from hyposalivation with cholinergic agents (such as bethanechol, pilocarpine, and cevimeline); provide careful follow-up to restore dry mouth caries.
- Provide follow-up for early detection of lymphoma (patients have up to a 44-fold increased risk).

ADENOMATOID (ACINAR) HYPERPLASIA

Lesion represents an *acinar* hyperplasia as opposed to *adenomatoid* ductal hyperplasia that occurs mostly in the parotid gland.

Clinical Findings

- Mostly found in adults; painless unilateral swelling of the palatal mucosa, usually without ulceration

Etiopathogenesis and Histopathologic Features

This condition represents a reactive hyperplasia of acini, is often seen in smokers and denture wearers, and is found adjacent to neoplasms or necrotizing sialometaplasia.

- Hyperplasia and hypertrophy is of mucous acini that are back to back (Figs. 12-33 and 12-34).
- Mild focal fibrosis, ductal dilatation, and chronic inflammation may be present.

Differential Diagnosis

- As with ductal adenomatoid hyperplasia, this may be an indication of an adjacent salivary gland neoplasm in the vicinity.

Management

- Excision is the treatment of choice.

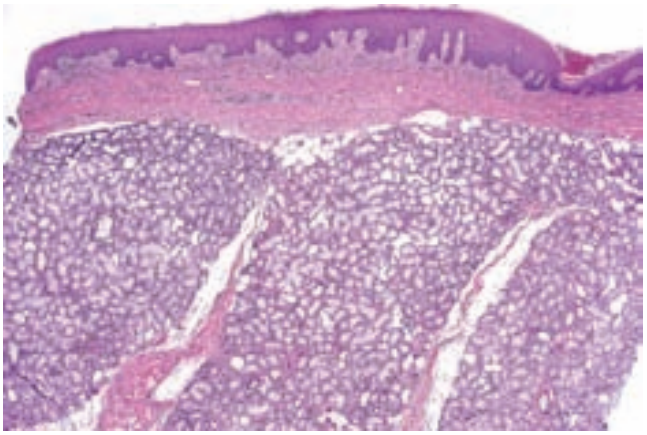

FIGURE 12-34. Adenomatoid hyperplasia of salivary glands: benign hyperplasia of acini.

SCLEROSING POLYCYSTIC ADENOSIS

This is a rare salivary gland disorder usually seen in the major glands, and infrequently in the minor glands. Some clinicians consider it a pseudoneoplastic inflammatory condition, whereas others consider it a true neoplasm.

Clinical Findings

- Nondescript movable nodule within the mucosa in adults in the fourth to fifth decade

Etiopathogenesis and Histopathologic Features

There is a mixture of metaplastic and cystic changes suggestive of fibrocystic disease and sclerosing adenosis of the breast. A recent study suggests that these lesions are clonal. Changes in minor glands are not as marked, and lesions are not as sclerotic as those in major glands.

- Lesions demonstrate tubuloacinar hyperplasia with ducts of varying sizes, reactive cytologic atypia, marked interstitial fibrosis, hyalinization, and variable chronic inflammation; cribriform or microcystic pattern may be noted (Figs. 12-35, *A* and *B,* and 12-36, *A*).
- Dilated ducts exhibit oncocytic, apocrine-like, clear cell, and mucous cell metaplasia with inspissation of secretions and foamy macrophages (see Figs. 12-35, *C* and *D,* and 12-36, *B*); collagenous spherules may be present; large eosinophilic PAS-positive inclusions are present in some acinar cells (altered zymogen granules) and within lumen.

Differential Diagnosis

- Adenoma and adenocarcinoma are unlikely because of the diverse cytologic features of oncocytic and mucous cell metaplasia; adenocarcinoma exhibits invasion of surrounding tissues.

Management

- Excision is treatment of choice and up to 30% of lesions recur, but carcinomatous transformation and metastases have not been reported.

13 Salivary Gland Neoplasms

CHAPTER CONTENTS

Only the most common benign and malignant lesions of minor glands will be discussed in this section. Intraoral minor salivary gland neoplasms account for 1% to 2% of nonhospital-based biopsy services, with 60% of these being benign. There is a female predominance.

In general, benign salivary gland neoplasms are diagnosed by histomorphology alone. Ductal cells show cytoplasmic positivity for AE1/3, CAM5.2, cytokeratin (CK) 5/6, CK7, and CK19, and sometimes CK14. Myoepithelial cells are immunopositive for pancytokeratin, S-100 protein, CK14, glial fibrillary acidic protein (GFAP) (mostly in the myxoid areas), calponin, smooth muscle actin, smooth muscle myosin long chain, maspin, and p63 (p63 also stains basal cells). Serous acinar cells stain for gross cystic disease fluid protein-15. Most tumors are thought to arise from the intercalated duct reserve cell or its precursor that differentiates into acinar, myoepithelial, striated, and intercalated ductal cells. The excretory duct reserve cell differentiates into excretory ductal cells and gives rise to tumors such as mucoepidermoid carcinoma and salivary duct carcinoma.

Benign Salivary Gland Neoplasms

Clinical Features

Benign salivary gland neoplasms manifest similarly regardless of the final histologic diagnosis. The pleomorphic adenoma (sometimes referred to as the benign mixed tumor) and myoepithelioma are the most common intraoral benign neoplasms (60% to 80% of all cases), followed by canalicular adenoma and cystadenoma. These tumors are putatively thought to arise from intercalated duct reserve cells within the secretory unit.

- Neoplasms are usually seen in adults as a painless nodule or mass, often mobile, usually covered by normal mucosa, although trauma may cause overlying ulceration.
- Palate is the most common site, followed by upper lip (90% of canalicular adenomas occur at this site) (Fig. 13-1).

PLEOMORPHIC ADENOMA AND MYOEPITHELIOMA

Etiopathogenesis and Histopathologic Features

This neoplasm putatively arises from the intercalated duct reserve cell (or its precursor) and differentiates toward ductal and myoepithelial elements, and it is the latter that gives this neoplasm its distinctive stromal appearance because of its ability to produce myxochondroid matrix, bone, and even fat. The term *myoepithelioma* is used by some pathologists to mean a myoepithelial cell–predominant neoplasm with few ducts, whereas other clinicians use that term only if no ducts are present, preferring the term *pleomorphic adenoma, myoepithelial predominant* for the former lesions.

- Partially or nonencapsulated tumor; proliferation of ducts with a cuff of epithelioid myoepithelial cells

with the myoepithelial cells merging into the myxochondroid stroma (Fig. 13-2, *A-E*); infiltration of the capsule a common finding (see Fig. 13-2, *F*); some tumors are cellular with little stroma, or may look fairly homogeneous, whereas other tumors are predominantly myxoid (Figs. 13-3 and 13-4)

- Myoepithelial cells positive for CK5/6, CK14, S-100 protein, GFAP, p63, calponin, smooth muscle actin, and smooth muscle myosin long chain (Fig. 13-5)
- Keratin pearls, osseous material, foci of mucous cells, oncocytes, mature fat, and crystalline material variably present (Figs. 13-6 to 13-8)
- Myoepithelial cells may be epithelioid, spindled, plasmacytoid, or clear; plasmacytoid myoepithelial cells having abundant eosinophilic cytoplasm and eccentric nuclei that vary in shape and size, dispersed chromatin, and small or inconspicuous nucleoli (Figs. 13-9 and 13-10)
- Significant cytologic atypia (not just variation in nuclear shape and size) seen in atypical pleomorphic adenoma, intracapsular carcinoma, or noninvasive carcinoma ex pleomorphic adenoma

Differential Diagnosis

- Aprocrine chondroid syringoma of the skin may appear identical, although there may be apocrine decapitation secretion within ducts and follicular and sebaceous differentiation.
- Spindle cell lipoma or other benign mesenchymal neoplasm/hamartoma with bone, cartilage, and fat differentiation do not show immunopositivity for keratin within the spindle cells.
- Plasmacytomas have coarse "clock-face" chromatin and the zone of Hopf and are S-100 and cytokeratin negative and CD138 positive.
- Presence of significant hyalinization must prompt a search for carcinoma or adenocarcinoma ex pleomorphic adenoma; myoepithelial carcinoma has been reported infrequently intraorally (Figs. 13-11 and 13-12).

Management and Prognosis

- Excision with clear margins is treatment of choice, and the recurrence rate is insignificant for intraoral lesions.
- Malignant transformation may occur in long-standing tumors, although this is a rare phenomenon.

CANALICULAR ADENOMA

Etiopathogenesis and Histopathologic Features

This tumor is likely to arise from intercalated duct reserve cells with differentiation toward ductal cells with minimal-to-no myoepithelial differentiation.

- Encapsulated proliferation of basaloid cells, usually in two layers, in anastomosing trabeculae and ribbon-like strands that enclose narrow, elongated ducts and channels (canaliculi); adenoma may be focally cystic; cells have spindled nuclei with dispersed chromatin and small nucleoli; collagen-poor, mucinous/myxoid stroma, sometimes hyalinized with prominent ectatic capillaries (Figs. 13-13 and 13-14); some tumor strands have multiple layers of epithelium resembling trabecular basal cell adenoma of the major glands (Fig. 13-15); generally negative for p63, smooth muscle actin, and other myoepithelial markers, but may be positive for S-100 protein.
- Foci of early canalicular adenoma within adjacent gland lobules is not unusual.

Differential Diagnosis

- Basal cell adenoma (usually in the major glands) has a distinct basal cell layer, lacks myxohyaline stroma, and often has basement membrane–like deposits.
- Low-grade adenocarcinoma lacks encapsulation and infiltrates adjacent structures.
- Ductal adenoma (striated duct adenoma) does not have the anastomosing strands of cells, but forms ducts that are p63 positive.
- Adenoid cystic carcinoma, tubular-type, contains angular, hyperchromatic nuclei and stains strongly for c-kit.

Management

- Enucleation or excision with clear margins is curative.

CYSTADENOMA, PAPILLARY OR OTHERWISE

Etiopathogenesis and Histopathologic Features

This tumor likely arises from the intercalated duct reserve cell.

- Encapsulated or well-circumscribed adenomatous proliferation of ducts, some of which form large cystic structures into which papillary structures with delicate fibrovascular cores protrude; cysts lined by one to two layers of low cuboidal-to-columnar cells, oncocytes, or mucous cells; nuclei have dispersed chromatin, small nucleoli, and insignificant mitotic activity (Figs. 13-16 to 13-18).

Differential Diagnosis

- Reactive multifocal metaplasia of ducts (sialocystosis) is nonencapsulated and shows cystically dilated ducts in multiple salivary gland lobules without adenomatous proliferation (see Salivary Duct Cyst in Chapter 12) (Fig. 13-19).
- Low-grade adenocarcinomas are nonencapsulated and infiltrative, although cytology may be bland.

Management

- Excision or enucleation with clear margins is curative.

SIALADENOMA PAPILLIFERUM

There are three papillary conditions that involve the salivary gland ducts: sialadenoma papilliferum, ductal papilloma, and inverted papilloma. A possible cell of origin is the excretory duct reserve cell located in the distal portions of the excretory duct.

Clinical Findings

- Rare lesion; most common location is the hard palate (80%) of middle-aged adults; buccal mucosa is second most common site.
- Lesion has a rough, warty appearance similar to papilloma.

Etiopathogenesis and Histopathologic Features

This is the salivary gland equivalent of the syringocystadenoma papilliferum of the skin.

- Benign exophytic papillary proliferation of surface squamous epithelium in continuity with deep adenomatous hyperplasia and dilatation of ducts present at the base of the lesion; ducts are lined by two layers of low columnar-to-cuboidal cells with occasional mucous cells; luminal palpillations are often present (Fig. 13-20); the degree of adenomatous proliferation varies.
- Ductal cells, as expected, stain for CK13 and CK19, and myoepithelial cells are present around the ducts.

Differential Diagnosis

- May be mistaken for squamous papilloma if the biopsy is small and superficial and does not include the deeper adenomatoid hyperplasia.
- Focal adenomatous and papillary hyperplasia may be part of an inflammatory and metaplastic process (Fig. 13-21).
- Occasional lesions have shown development of dysplasia or other salivary gland malignancies, but these must be carefully distinguished from papillary adenocarcinomas that secondarily involve the surface mucosa.

Management

- Excision is the treatment of choice; lesion does not recur.

INTRADUCTAL PAPILLOMA

Clinical Findings

- Painless nodules or masses on the lips or buccal mucosa in middle-aged or older adults

Histopathologic Features

- This lesion arises within a cystically dilated excretory salivary duct; within the lumen is a benign papillary proliferation of cuboidal and columnar cells, squamous cells, and mucous cells with fibrovascular cores; microcysts are often present; the point of origin/attachment to the duct lumen may be evident (Fig. 13-22).

Differential Diagnosis

- Papillary cystadenoma consists of a proliferation of cysts and ductal structures that exhibit papillary structures (see earlier).
- Inverted ductal papilloma is endophytic and forms bulbous fronds of epithelium that pushes into the connective tissue (see earlier).

Management and Prognosis

- Excision is curative.

INVERTED DUCTAL PAPILLOMA

Clinical Findings

- Lesion occurs in middle-aged or older adults; nodule is within lip and buccal mucosa in 70% of cases.

Etiopathogenesis and Histopathologic Features

This lesion is similar to a sinonasal inverted papilloma.

- Unencapsulated, discrete lobular and endophytic proliferation of squamous epithelium arises from an excretory salivary duct; clefts within the lobules represent extensions of the duct, and they are lined by low cuboidal-to-columnar cells; clusters of mucous cells, oncocytes, and microcysts are often seen (Fig. 13-23).
- Lesions are positive for CK14 and CK19; rare cases show the presence of human papillomavirus-6 and -11.

Differential Diagnosis

- Mucoepidermoid carcinomas may have a predominantly epidermoid component with only a few mucous cells but are infiltrative and often cystic.
- Intraductal papillomas generally have one large cyst with an intraluminal papilloma.

Management and Prognosis

- Excision is curative; lesion does not tend to recur.

Malignant Salivary Gland Neoplasms

Clinical Features

The clinical appearance of malignant salivary gland neoplasms are similar, regardless of the final histologic diagnosis.

- Tumors appear as firm masses, mobile or tethered, ulcerated or cystic (especially mucoepidermoid carcinoma) on hard palate, upper lip, floor of mouth and tongue; usually in middle-aged and older adults, with 2:1 female predilection (Fig. 13-24).

The mucoepidermoid carcinoma is the most common intraoral salivary gland malignancy (also the most common in childhood); others include polymorphous low-grade adenocarcinoma, adenoid cystic carcinoma, acinic cell carcinoma, hyalinizing clear cell carcinoma, and cribriform adenocarcinoma of the tongue.

- Although tumors may show low recurrence and moderate to high survival rates at 5 years, recurrence and metastases often occur many years after the initial diagnosis.

General Histopathologic Considerations

It is believed that most tumors arise from the intercalated duct reserve cell or its precursor with differentiation toward ductal, myoepithelial, acinar, oncocytic, clear, and nonspecific glandular cells. The mucoepidermoid carcinoma arises from the excretory duct reserve cell or its precursor.

- Most malignant salivary gland tumors are diagnosed by pattern of growth and morphology; infiltration of the stroma and the adjacent glands and perineural invasion are important features.
- Benign-appearing tumor cells and lack of mitotic activity is the norm for many low-grade salivary gland malignancies.
- Tumor-associated lymphoid proliferation is particularly common in acinic cell carcinoma and mucoepidermoid carcinoma, and it should not be mistaken for metastasis within a lymph node.
- High Ki-67 index may be predictive of poorer survival in some tumors, such as adenoid cystic and acinic cell carcinomas, whereas low expression of c-kit and high expression of epidermal growth factor receptor may also be associated with poorer survival in some tumors.

MUCOEPIDERMOID CARCINOMA

Histopathologic Features

- Nonencapsulated proliferation of mucous, epidermoid, columnar, and intermediate cells that invade the stroma; cysts of varying sizes are usually present, and ductal structures are noted (Figs. 13-25, *A-C* and 13-26, *A* and *B*); some low-grade tumors consist of a

Mucoepidermoid carcinoma: a clinicopathologic study of 80 patients with special reference to histological grading. *Am J Surg Pathol.* 2001;25:835-845; Goode RK, Auclair PL, Ellis GL. Mucoepidermoid carcinoma of the major salivary glands: clinical and histopathologic analysis of 234 cases with evaluation of grading criteria. *Cancer.* 1998;82:1217-1224.
HPF, High-power field.

single large cyst with tumor plaques in the lining; intermediate cells vary from the small cells with scant cytoplasm and dark nuclei to larger, polygonal cells with pale nuclei and inconspicuous nucleoli (see Fig. 13-25, *D*); perineural invasion may be present (see Fig. 13-25, *E*).

- Mucous cells are mucicarmine positive (see Fig. 13-26, *C*); there is insignificant myoepithelial differentiation.
- Clear cell (glycogen or mucin positive) (Fig. 13-27) and oncocytic variants (usually in the parotid gland) are noted, but small populations of these cells may be present in conventional mucoepidermoid carcinoma.
- Sclerosing mucoepidermoid carcinoma has been reported as a variant with marked sclerosis, stromal eosinophils, and tumor-associated lymphocyte proliferation (Fig. 13-28).
- Grading depends on the presence of cysts, mitotic activity, necrosis, hemorrhage, and perineural invasion and correlates with the prognosis; it is an important prognostic factor (Table 13-1); up to 80% of tumors are low grade; Ki-67 index is not predictive of grade.
- Presence of p53 may predict recurrence.

Differential Diagnosis

- Cystadenocarcinomas do not consist of predominantly epidermoid and mucous cells.
- Acinic cell adenocarcinoma has a more uniform appearance, is often papillary, and it contains cells with zymogen granules (periodic acid–Schiff [PAS] stain positive and diastase resistant).

Management and Prognosis

- Excision with clear margins is the treatment of choice; radiotherapy may help to improve local control in selected cases.
- Two histologic grading systems are currently in use with slight variation in criteria (see Table 13-1); 3% and 80% of intraoral low-grade and high-grade tumors, respectively, metastasize or lead to death of the patient.

ADENOID CYSTIC CARCINOMA

Histopathologic Features

- Cribriform (classic "Swiss cheese") pattern: there are lobules and islands of tumor cells with multiple small pseudoducts or true ducts; pseudoducts contain glycosaminoglycans or basement membrane material and are surrounded by myoepithelial cells (Figs. 13-29, *A-E,* and 13-30, *A-C*); true ducts are composed of low cuboidal cells with eosinophilic cytoplasm, round nuclei, and indistinct nucleoli and are surrounded by myoepithelial cells; the latter have hyperchromatic, angulated nuclei and coarse chromatin, small nucleoli, and clear cytoplasm (primarily in the cribriform pattern).
- Tubular pattern: true ducts surrounded by myoepithelial cells; most tumors have a combination of cribriform and tubular patterns (Fig. 13-31).
- Solid pattern: cells are basaloid with less angulated nuclei, small nucleoli, and more mitotic activity; perineural invasion is present in one third of cases (see Fig. 13-30, *D*); tumors with >30% solid component have higher Ki-67 index, higher rate of recurrence, and poorer 5-year survival, and they should be reported as such.
- C-kit and p63 are consistently and strongly positive in the luminal and abluminal myoepithelial cells, respectively (see Fig. 13-29, *F* and *G*); CD43 is positive in 50% to 100% of cases and may be useful in diagnosis of some problematic cases; lack of c-kit and high Ki-67 index may adversely affect survival.
- Dedifferentiation leads to foci of tumor cells with high-grade morphology and this occurence is more common in the major glands.

Differential Diagnosis

- Polymorphous low-grade adenocarcinoma has multiple patterns of growth and bland cytology; the cells do not usually stain significantly for myoepithelial markers, and they are only weakly positive for c-kit (see later).
- Epimyoepithelial carcinoma is rare in the minor glands and the biphasic pattern of ductal cells with surrounding myoepithelial cells is fairly consistent throughout the tumor.

Management and Prognosis

- Wide excision with clear margins is the treatment of choice.
- Overall 5-year and 15-year survival is 60% to 80% and 25% to 40%, respectively; tumors generally exhibit persistence and recurrence with late-onset metastases to the lungs, lymph nodes, and bones; tumors with greater than 30% solid component have a poorer prognosis; 10-year survival for p53-positive and -negative tumors is 8% and 34%, respectively; for c-kit, it is 12% and 34%, respectively.

- Perineural invasion, oropharyngeal site (versus oral site), and high tumor stage adversely affect local recurrence rate and disease-free survival.

POLYMORPHOUS LOW-GRADE ADENOCARCINOMA

This tumor represents 10% to 15% of all intraoral salivary gland neoplasms and 20% to 25% of malignant tumors.

Histopathologic Features

- Infiltrative tumor is polymorphic in architecture, forming solid sheets, ducts, trabeculae, cribriform structures, and small islands and strands of cells; linear cords of cells in single array are often seen at the periphery of the tumor and near the mucosal surface; thin strands and cords of cells often have a swirling or target-like pattern; stroma is often myxochondroid (Figs. 13-32, *A* and *B,* 13-33, *A-C,* 13-34, *A-C*).
- Cells are isomorphic with indistinct cytoplasmic outlines, pale cytoplasm, ovoid-to-round nuclei with fine, dispersed chromatin, small nucleoli, and generally few-to-no mitoses (see Figs. 13-32, *C,* 13-33, *D,* and 13-34, *D*); stroma is variably hyalinized and myxoid; perineural invasion is common (50% to 75% of cases) but has little prognostic significance (see Figs. 13-33, *E,* and 13-34, *E*); invasion of bone is present in 25% of cases.
- Focal nests of oncocytes, clear cells, mucous cells and crystalloid bodies similar to pleomorphic adenoma may be seen; cells are weakly reactive for c-kit.

Differential Diagnosis

- Pleomorphic adenoma and myoepithelioma may show capsular infiltration but no perineural invasion; presence of plasmacytoid myoepithelial cells, cartilage, and fat and bone support a diagnosis of pleomorphic adenoma.
- Adenoid cystic carcinoma cells have hyperchromatic, large nuclei with irregular outlines; pattern is more predictably cribriform, tubular, and solid and studies for c-kit are consistently and strongly positive within ductal cells.
- Tumors with a predominantly papillary growth pattern are more likely to be papillary adenocarcinomas.
- Cribriform adenocarcinoma (of minor salivary glands) is likely a separate entity, rather than a variant of polymorphous low-grade carcinoma, and tends to involve the tongue although not exclusively; lobular epithelial proliferation is in a cribriform, solid, and microcystic pattern with differentiation toward small, single-cell population showing myoepithelial differentiation; the tumor does not demonstrate

single filing or strands of cells seen in polymorpolymorphous low-grade adenocarcinoma; cells are isomorphic, and nuclei tend to be clear and overlap similar to papillary thyroid carcinoma; most tumors have already metastasized to cervical nodes when first diagnosed (Fig. 13-35); cells are positive for basal and myoepithelial cell markers (such as S-100 protein, vimentin, calponin, and p63), CK7, c-kit, and p16 and negative for thyroid transcription factor 1 (TTF-1) and EMA.

Management and Prognosis

- Complete surgical excision is the treatment of choice; adjuvant radiation therapy is used in selected cases.
- Recurrence occurs in 9% to 30% of cases, often more than 5 years from diagnosis; metastases occur in up to 9% of cases; death from this tumor is rare.

ACINIC CELL ADENOCARCINOMA

The buccal mucosa and lip are the two most common sites for this neoplasm. It is the second most common salivary gland malignancy in children after mucoepidermoid carcinoma and constitutes less than 5% of malignant intraoral salivary gland tumors. It is much more common in the major glands.

Histopathologic Features

- Infiltrative tumor with four major patterns—solid, microcystic, papillary-cystic, and follicular; most tumors show a mixture of patterns.
- Archetypal tumor cell resembles serous cell with many hematoxyphilic zymogen granules and small, dark, eccentric nucleus (Fig. 13-36, *A-D*); may be present only in small numbers and PAS stain shows diastase-resistant granules (see Fig. 13-36, *E*); intercalated ductal cells form ducts, are smaller and cuboidal with amphophilic cytoplasm and central round-to-ovoid nuclei with dispersed chromatin and small nucleoli (Fig. 13-37); nonspecific glandular cells form a syncytium and appear somewhat nondescript; foci of mucous cells, vacuolated cells, and clear cells are frequently seen (Fig. 13-38).
- High Ki-67 index may be associated with poorer prognosis.
- Tumor-associated lymphoid proliferation is common and should not be misinterpreted as metastatic disease.
- Dedifferentiated tumors consist of undifferentiated and pleomorphic cells with higher mitotic activity (more common in major glands).

Differential Diagnosis

- Mucoepidermoid carcinoma has epidermoid/squamous component and significant population of mucous cells.
- Papillary cystadenocarcinoma does not contain zymogen granules.

Management and Prognosis

- Surgical excision is the treatment of choice; adjuvant radiation therapy may be helpful only in selected cases.
- Staging is probably the only parameter that correlates with prognosis; intraoral tumors tend to behave less aggressively compared with those in the major glands, where recurrence rate is 12%, metastatic rate is 8%, and 6% of patients die of their disease.

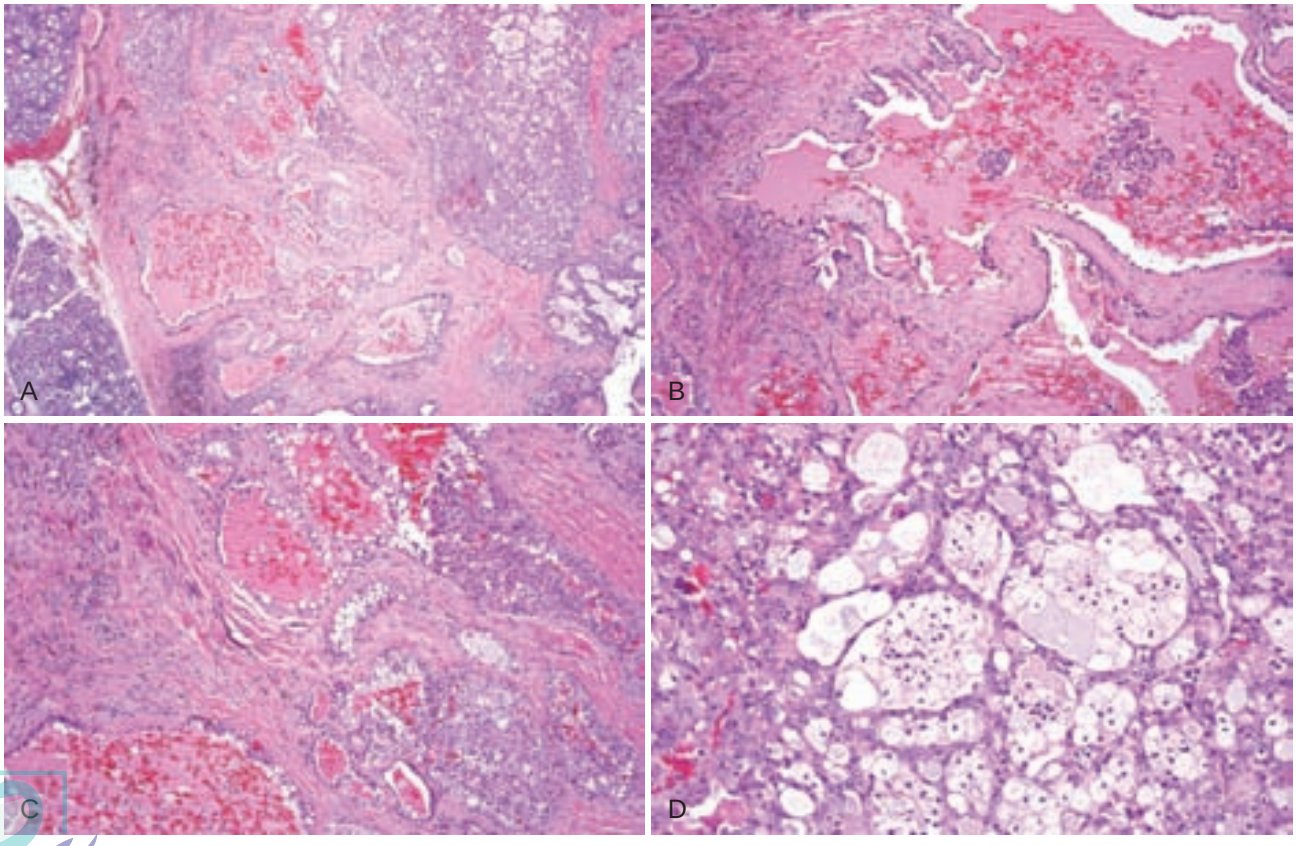

FIGURE 13-38. Acinic cell adenocarcinoma. **A,** Focal areas that are papillary-cystic (*bottom right*). **B,** Tumor forms papillary structures within cyst lumen. **C,** Clear cells are noted focally. **D,** Microcystic and reticular pattern with many vacuolated cells.

CLEAR CELL ADENOCARCINOMA (HYALINIZING)

Histopathologic Features

- Infiltrative proliferation of sheets, cords, nests, and trabeculae of monomorphic clear cells that are round to polygonal with variable degrees of stromal hyalinization; ovoid nuclei with dispersed chromatin and small-to-inconspicuous nucleoli; mitoses are rare (Fig. 13-39, *A-C*); cells are glycogen rich (see Fig. 13-39, *D* and *E*); some cases are not hyalinized, and rare cases do not contain glycogen.
- One third of cases exhibit perineural invasion; atypia and necrosis are rare.
- All cases are AE1/3 positive; epithelial membrane antigen (EMA) is positive in the majority of cases, and carcinoembryonic antigen (CEA) is positive in some cases; myoepithelial markers are negative.

Differential Diagnosis

- Clear cell mucoepidermoid carcinoma contains many mucous cells and epidermoid cells.
- Clear cell variant of acinic cell carcinoma has abundant PAS-stain positive, diastase-resistant zymogen granules within the tumor cells.
- Epithelial-myoepithelial carcinoma is rare in the oral cavity and is biphasic with ductal cells surrounded by clear myoepithelial cells.
- Clear cell myoepithelial neoplasms are diffusely immunopositive for myoepithelial markers.
- Metastatic renal cell carcinoma contains nests of tumor cells with numerous interspersed capillaries (Fig. 13-40).
- Clear cell odontogenic carcinoma occurs within bone, exhibits significant cytologic atypia, and is generally a high-grade lesion.

Management and Prognosis

- Excision with clear margins is the treatment of choice; radiotherapy may be indicated.
- Metastases develop in 16% to 25% of patients; most metastases are to regional nodes, but patients do not die of the tumor.

ADENOCARCINOMA, NOT OTHERWISE SPECIFIED

Adenocarcinoma, not otherwise specified, constitutes less than 10% of cases of intraoral malignant salivary gland tumors, but this frequency varies greatly. The tumor forms ductal structures, but it does not fit any of the defined salivary gland malignancies and is therefore a diagnosis of exclusion.

Histopathologic Features

- Adenocarcinoma, not otherwise specified, is an infiltrative neoplasm that forms ductal and glandular structures and may exhibit a variety of patterns including nests, tubules, cords and strands, trabeculae, or solid sheets (Fig. 13-41); because cytologic atypia is often minimal, the presence of infiltration at the tumor margin is one of the most important criteria that separates benign from malignant processes.

Differential Diagnosis

- Defined salivary gland malignancies such as polymorphous low-grade adenocarcinoma that has a polymorphic pattern, or less common forms of well-known entities, such as solid or tubular adenoid cystic carcinoma, should be ruled out.

Management and Prognosis

- Surgical excision is the treatment of choice with adjuvant radiation therapy for selected cases.
- As expected, tumors with high-grade cytology, necrosis, perineural invasion, and infiltration of normal structures are associated with locoregional recurrence.

14 Odontogenic Cysts

CHAPTER CONTENTS

The tooth develops from ingrowth of the lining of the primitive stomodeum called the dental lamina. The dental lamina forms tooth buds for the primary and the permanent dentition (Fig. 14-1), and after odontogenesis, remnant epithelium are left behind as rests. The epithelium of odontogenic cysts is thought to arise from stimulation of such residual odontogenic rests (e.g., rests of Serres in the gingiva or rests of Malassez around the tooth roots in the jawbones) (Fig. 14-2).

Odontogenic Cysts

Cystic lesions in the jawbones are either odontogenic or nonodontogenic in their derivation. All odontogenic cysts are inflammatory, developmental, or, less commonly, neoplastic in nature, and the putative epithelium from which they derive may be rests of Malassez, dental lamina rests, reduced enamel epithelium, degenerated enamel organ, or, in rare cases, the epithelium of the surface mucosa (Fig. 14-3). In general, inflammatory odontogenic cysts have proliferative epithelium, and developmental odontogenic cysts have uniformly thin epithelium, although inflammation may lead to epithelial proliferation. The most common cyst is the radicular cyst (>50%), followed by the dentigerous cyst and keratocystic odontogenic tumor (odontogenic keratocyst).

Inflammatory Cysts

APICAL AND LATERAL RADICULAR CYST AND PERIAPICAL GRANULOMA

A tooth that has caries involving the pulp or that has experienced direct trauma becomes devitalized and may develop a radiolucency at the apex of the root. This may represent an apical radicular cyst, periapical granuloma or scar, or abscess.

Clinical Findings

- A cyst may or may not manifest as a swelling, depending on the size; the tooth may or may not be painful; a well-circumscribed radiolucency is present at the apex (apical radicular) or on the side (lateral radicular) of a nonvital tooth; there may have been prior root canal (endodontic) therapy (Fig. 14-4, *A* and *B*).
- Residual cyst refers to any odontogenic cyst in the alveolar bone where a tooth had been extracted and is most often a residual apical radicular cyst (see Fig. 14-4, *C*)

Etiopathogenesis and Histopathologic Features

Inflammation from the pulp of necrotic teeth results in proliferation of rests of Malassez, which are remnants

of the Hertwig root sheath that helps form the roots of the teeth during odontogenesis.

- A radicular cyst is lined by nonkeratinized stratified squamous epithelium that usually proliferates in a plexiform or retiform pattern and exhibits spongiosis and neutrophilic exocytosis; the wall is composed of edematous granulation tissue and often scar tissue, many plasma cells, Russell bodies, lymphocytes, foamy macrophages, and sometimes abscesses are present (Fig. 14-5); curetted specimens may show only granulation tissue with focal lining epithelium (Fig. 14-6).
- Hyaline lamellar or globular structures of odontogenic origin (Rushton bodies) may be present within the epithelium (Fig. 14-7); epithelial loss is often associated with cholesterol granulomas.
- Foreign material from root canal filling is often seen: gutta percha is yellowish or brownish green, granular, and slightly refractile (Fig. 14-8); cements, in particular epoxy resin (such as AH Plus [Dentsply International, York, Pa], which contains zirconium and iron oxides and calcium tungstate), is usually refractile and crystalline in an eosinophilic background (Fig. 14-9); amalgam tattoo may be present from previous root apex excision (apicoectomy).
- Hyaline ring (pulse) granuloma (likely a foreign body reaction to exogenous material) consists of hyalinized rings with central and/or surrounding giant cells; foreign material is sometimes identified (Figs. 14-10 and 14-11).
- Radicular cysts from the apices of maxillary molars may be lined by respiratory epithelium (Fig. 14-12); fragments of sinus mucosa, however, signify an oroantral communication and must be reported; fragments of sinus inflammatory polyps may be present—exhibiting few to no mucous glands, eosinophilic coagulum, and eosinophils (Fig. 14-13).

Differential Diagnosis

- Any inflamed intraosseous, odontogenic, or other cyst may appear similar.
- If epithelium is not present, the diagnosis is periapical granuloma (Fig. 14-14); sheets of plasma cells are common in periapical granulomas, and they should not be overdiagnosed as plasmacytomas (Fig. 14-15).
- Periapical scar shows only fibrosis, sometimes with inflammation (Fig. 14-16).
- Chronic active periodontal disease appears similar histologically, but clinically, the tooth is surrounded by a periradicular radiolucency; disease starts either from an apical radicular cyst that grows very large and combines with an overlying periodontal bone defect or from periodontal disease starting from the surface of the bone and extending downwards to encompass the entire tooth.

Management and Prognosis

- Enucleation or curettage with apicoectomy (excision of the root tip) is curative.

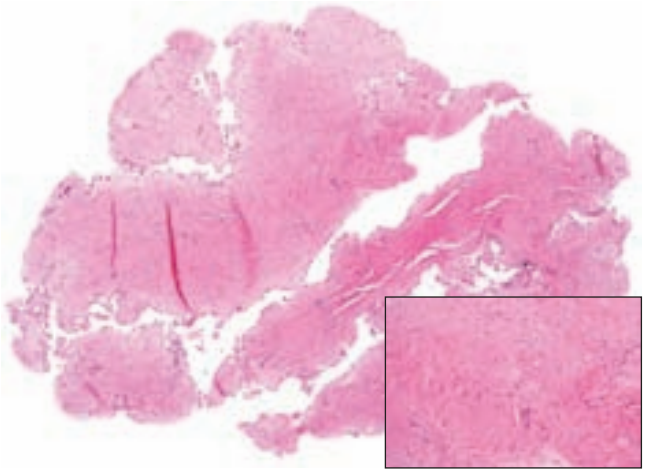

FIGURE 14-16. Periapical scar: dense fibrous scar tissue (*inset*).

MANDIBULAR BUCCAL BIFURCATION CYST

Clinical Findings

- Children in the first decade (mean age of 7 years); 38% bilateral
- Swelling and pain in the area of the first permanent molar; radiolucency around a vital first molar that extends from the furcation (where roots diverge) to the apex of the tooth causing tilting of the roots lingually (best seen on occlusal radiograph); periosteal reaction usually present (Fig. 14-17)

Etiopathogenesis and Histopathologic Features

Lining may derive from dental lamina rests or crevicular epithelium. Another theory of pathogenesis is that this arises from a laterally displaced dentigerous cyst, which could explain the high incidence of bilaterality.

- Similar to radicular cyst with proliferative epithelium and acute and chronic inflammation

Differential Diagnosis

- Some clinicians consider the buccal bifurcation cyst a subcategory of paradental cysts, which are cysts located to the side of a tooth; the most common locations are on the buccal or distal aspect of an erupted third molar that occurs in patients in the second and third decades are likely to represent a buccally or distally displaced and inflamed dentigerous cyst; some of these are associated with buccal enamel extensions that putatively cause periodontal pocketing; most patients have a history of third molar infection/pericoronitis.

Management and Prognosis

- Enucleation of the cyst without extraction of the tooth is curative for the buccal bifurcation cyst.
- Extraction of the tooth and enucleation of the paradental cyst associated with the third molar is curative.

Developmental Cysts

These cysts are characterized by uniformly thin lining, although inflammation will cause epithelial proliferation with spongiosis and neutrophilic exocytosis. Melanin pigment is infrequently encountered within developmental odontogenic cysts. The pluripotentiality of the lining of dentigerous and other developmental odontogenic cysts is the likely origin of intraosseous salivary gland neoplasms, most of which are malignant. The most common is mucoepidermoid carcinoma, followed by adenoid cystic carcinoma.

DENTIGEROUS CYST (FOLLICULAR CYST)

Clinical Findings

- Usually in the second and third decades; radiolucency associated with impacted teeth, usually the third molars, but also often the maxillary canines, premolars, and supernumerary teeth; well-demarcated unilocular radiolucency (Fig. 14-18)

Etiopathogenesis and Histopathologic Features

The epithelium is derived from reduced enamel epithelium (fused external and internal enamel epithelium after the tooth is formed) that has undergone squamous metaplasia as part of cystification. This epithelium is pluripotent and capable of producing mucous cells, ciliated cells, and glandular structures; intraosseous salivary gland neoplasms likely derive from these pluripotent cells. Some radiolucencies described by clinicians as dentigerous cysts maintain a lining of reduced enamel epithelium and, by custom, a diagnosis of dentigerous cyst, although they may actually represent hyperplastic dental follicles.

- Lining consists of nonkeratinized stratified squamous epithelium 5 to 10 cells thick (Figs. 14-19); some radiolucencies described by clinicians as dentigerous cysts maintain a lining of reduced enamel epithelium, a double layer of luminal columnar cells, and basal low cuboidal cells with eosinophilic cytoplasm, and a diagnosis of dentigerous cyst is made, although they may actually represent hyperplastic dental follicles (Fig. 14-20). Inflammation results in epithelial proliferation and spongiosis, and cholesterol granulomas are often seen where epithelium is disrupted (Fig. 14-21); mucous cells or ciliated cells are sometimes present (Fig. 14-22); the wall consists of dental follicle (see later); the overlying oral mucosa may be inflamed, especially if the patient is symptomatic (pericoronitis).
- The dental follicle is composed of delicately and sometimes more densely collagenized fibrous tissue with a distinctly myxoid/mucinous background; islands and strands of odontogenic epithelium are present, often with clear cells that sometimes exhibit peripheral stromal hyalinization (Fig. 14-23); perivascular hyalinization is common (see Fig. 14-19); these may be lined by reduced enamel epithelium.
- Dental papilla from an impacted tooth is composed of myxoid tissue in a rounded configuration lined by

odontoblasts (Fig. 14-24); these are often mistaken for odontogenic myxoma.

- Between 1% and 2% of radionuclencies associated with impacted teeth are histologically keratocystic odontogenic tumors (odontogenic keratocysts); 1% to 2% represent other benign odontogenic neoplasms; less than 1% are associated with the development of mucoepidermoid carcinoma (see later), ameloblastoma, and infrequently, squamous cell carcinoma (Figs. 14-25 and 14-26) (see Chapter 15).
- Follicular hamartomas with dystrophic calcifications and epithelial rests are seen in patients (usually blacks) with amelogenesis imperfecta and gingival hyperplasia.

Differential Diagnosis

- Other developmental odontogenic cysts, if lined by nonkeratinized squamous epithelium, may appear similar.
- A diagnosis of hyperplastic dental follicle is made if follicular tissue is present that may or may not be lined by reduced enamel epithelium, if the clinical impression is such.
- Eruption cysts are bluish cystic areas overlying an erupting tooth with no intervening bone (Fig. 14-27); they are lined by nonkeratinized stratified squamous epithelium.
- Odontogenic myxomas are more uniformly myxoid without lining epithelium, and central odontogenic fibromas are more collagenous with islands and strands of odontogenic epithelium (see Chapter 15).

Management

- Enucleation or curettage with removal of tooth is curative.

LATERAL PERIODONTAL CYST

Clinical Findings

- Unilocular radiolucency is evident between two teeth that are vital; most common location is between the premolars, followed by the canine-lateral area (Fig. 14-28); rare cases are multifocal.
- Multiloculated radiolucency in the same locations may represent botryoid odontogenic cyst; mandible is involved in 80% of cases.

Etiopathogenesis and Histopathologic Features

Epithelium is derived from rests of dental lamina.

- Epithelium is uniformly three to eight cells thick and composed of nonkeratinized stratified squamous or low cuboidal cells, with epithelial plaques composed of clear cells that contain glycogen and may have a swirling, whorled morphology (Figs. 14-29 and 14-30).
- Multilocular variant is botryoid odontogenic cyst (Fig. 14-31).

Management and Prognosis

- Enucleation or curettage is curative for the conventional lateral periodontal cyst.
- Botryoid odontogenic cyst recurs in as many as 18% to 30% of cases, especially if multiloculated radiographically.

ORTHOKERATINIZED ODONTOGENIC CYST

This cyst is not to be confused with the keratocystic odontogenic tumor (odontogenic keratocyst) (see Chapter 15).

Clinical Features

- Most common in third and fourth decades, with 3:1 male predilection; unilocular radiolucency in the posterior mandible/ramus (90%), one half of cases associated with impacted tooth (Fig. 14-32); no association with nevoid basal cell carcinoma syndrome

Etiopathogenesis and Histopathologic Features

Cyst likely arises from dental lamina rests and resembles epithelial inclusion (epidermoid) cyst (see Chapter 2).

- Uniformly 5 to 15 cells thick with *ortho*keratin and granular layer; no palisading of basal cell nuclei and flat interface without inflammation; keratinaceous material in lumen; no satellite cysts in wall (Fig. 14-33); Ki-67 confined to scattered cells in the basal layer and p63 to basal and suprabasilar cells

Differential Diagnosis

- If parakeratin is present even focally, a diagnosis of keratocystic odontogenic tumor (odontogenic keratocyst) must be made.

Management and Prognosis

- Excision or curettage is curative; recurrence rate is insignificant.

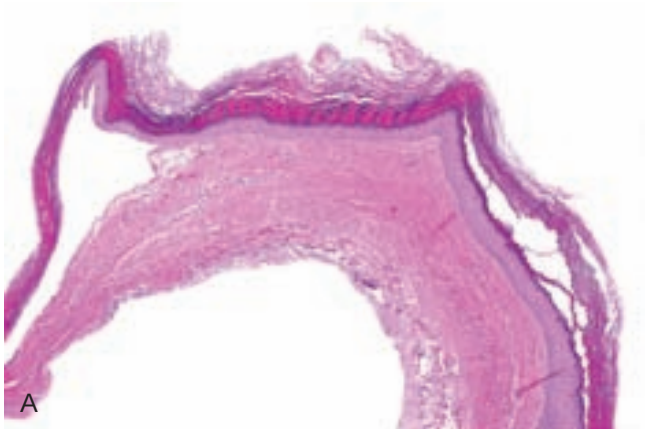

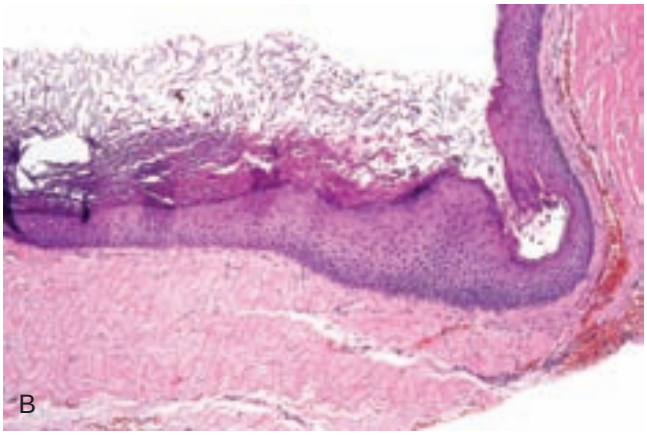

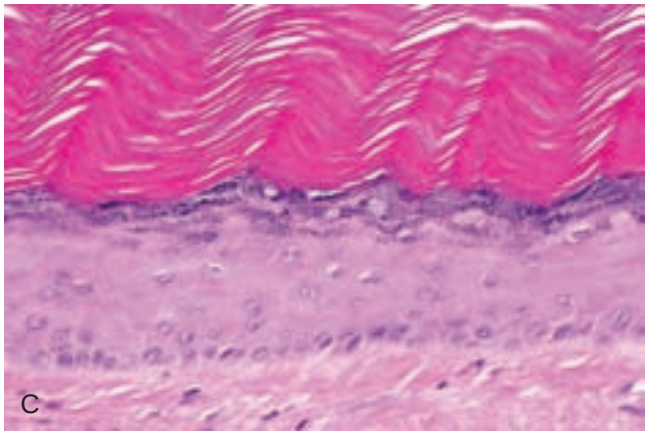

FIGURE 14-33. Orthokeratinized odontogenic cyst. **A,** Cyst lined by thickly orthokeratinized epithelium of variable thickness with no inflammation. **B,** Epithelium is orthokeratinized with granular layer. **C,** Basal cells do not show palisading of nuclei.

ODONTOGENIC CYST IN A GLOBULOMAXILLARY LOCATION

This cyst once was classified as a fissural cyst but has been reclassified as an odontogenic cyst because there is no fusion of fissures in this area, but rather erasure of the fissure by ectomesenchyme.

Clinical Findings

- Pear-shaped radiolucency is evident between the canine and maxillary lateral incisor.

Etiopathogenesis and Histopathologic Features

Two pieces of evidence that support an odontogenic origin are that approximately 10% are keratocystic odontogenic tumor (odontogenic keratocyst), and Rushton bodies are sometimes noted—two features not seen in fissural cysts. They may also histologically be radicular cysts, lateral periodontal cysts, or other developmental odontogenic cyst. It could even represent a lateral dentigerous cyst from the maxillary canine, which tends to erupt late, is often impacted and is often associated with a conventional dentigerous cyst. The current practice is to identify the cyst specifically as one of the aforementioned entities, rather than use the term *globulomaxillary cyst.*

- Nondescript nonkeratinized stratified squamous epithelium of variable thickness; inflammation may be present; presence of Rushton bodies confirms odontogenic origin (Fig. 14-34); keratocystic odontogenic tumor (odontogenic keratocyst) must be reported as such.

Management and Prognosis

- Excision is curative.

PRIMORDIAL CYST

Clinical Features

- Unilocular radiolucency that develops in place of a tooth (may be a supernumerary such as a mesiodens that occurs in the midline of the maxilla)

Etiopathogenesis and Histopathologic Features

Epithelium is derived from degeneration of the enamel organ without formation of a tooth.

- Epithelium is nondescript nonkeratinized stratified squamous and generally 5 to 10 layers thick; mucous and ciliated cells may be present if an impacted tooth had been extracted from the same area.
- Approximately 45% to 50% of primordial cysts are keratocystic odontogenic tumor (odontogenic keratocyst), but these two terms should not be used interchangeably.

Differential Diagnosis

- Residual dentigerous cyst should be considered if an impacted tooth had been extracted from the same area.

Management and Prognosis

- Enucleation or complete curettage is curative for cysts lined by nonkeratinized epithelium (see Chapter 15 for management of keratocystic odontogenic tumor [odontogenic keratocyst]).

GLANDULAR ODONTOGENIC CYST

Lesion may represent a cystic neoplasm because of its locally aggressive behavior and high recurrence rate, but at this time, it is still classified as a cyst.

Clinical Findings

- Uniloculated or multiloculated radiolucency is seen in adults in the fifth to seventh decade; lesions occur more often in the mandible (80%) and cause jaw expansion; 60% of lesions involve anterior portions of the jaws, and multiloculated lesions tend to be larger; lesions are associated with tooth displacement or root resorption (25%-50%), or impacted tooth (11%) (Fig. 14-35); cortex perforation is seen in 60% of cases.

Etiopathogenesis and Histopathologic Features

Lesion likely arises from rests of dental lamina.

- Lined by nonkeratinized stratified squamous or basaloid epithelium with scattered mucous cells and ductlike or microcystic structures; parts of the cyst may be lined by nondescript, uniformly thin epithelium (Figs. 14-36, *A-C*); multiple cystic compartments usually are present, and luminal cells and cells forming ducts are cuboidal with eosinophilic cytoplasm and often show evidence of secretory activity and "snouting" (see Fig. 14-36, *D*); epithelial plaques and clear cells often present; focal islands resembling mucoepidermoid carcinoma of unknown significance may be present.
- Lesion is positive for CK5/6 and CK7, and there is variable staining for calponin; lesion is negative for S-100 and SMA.

Differential Diagnosis

- Dentigerous cyst may show mucous cell metaplasia and ductlike structures focally (Fig. 14-37).
- Mucoepidermoid carcinoma shows invasion of the stroma by large polygonal epidermoid cells, intermediate cells, and mucous cells.
- Cysts with epithelial plaques alone are more likely botryoid odontogenic or lateral periodontal cysts.

Management and Prognosis

- Peripheral ostectomy, en bloc resection, or marginal resection are the treatments of choice; larger lesions, cortical perforation, and enucleation and curettage are associated with higher rate of recurrence that varies from 14% to 30%.

15 Odontogenic Tumors

CHAPTER CONTENTS

Odontogenic tumors are classified as follows: (1) those that produce mainly epithelium with mature fibrous stroma without ectomesenchyme; (2) those that produce epithelium with ectomesenchyme; and (3) those that produce mainly ectomesenchyme with or without epithelium (usually rests) (Fig. 15-1). Those that produce significant amounts of calcified tissues will contain radiopacities. Some odontogenic neoplasms exhibit histologic patterns of several tumors, and these are called combined, or hybrid odontogenic tumors. Any of these benign neoplasms may have peripheral (extraosseous), as well as malignant, counterparts, and only the more common malignant tumors will be discussed here. Epithelial tumors are likely to derive from rests of dental lamina, and mesenchymal tumors derive from precursor mesenchymal cells that recapitulate formation of the dental papilla, follicle, and osteocementum.

Epithelial Tumors without Ectomesenchyme

KERATOCYSTIC ODONTOGENIC TUMOR (ODONTOGENIC KERATOCYST)

This entity has been reclassified as a cystic neoplasm because of its locally aggressive behavior, high proliferation indices, presence of p53 and p63 in suprabasal cells, and in cases associated with the nevoid basal cell carcinoma syndrome—as well as some sporadic cases—loss of heterozygosity of the tumor suppressor gene *PTCH*, mapped to chromosome 9q22.3-q31.

Clinical Findings

- Forty percent of sporadic cases occur in the third and fourth decades with 2:1 male predilection.
- Radiolucency may be uniloculated (>80% of cases) or multiloculated, usually in the posterior mandible (70% of cases); one third to one quarter are associated with an impacted tooth; cyst contents are cheesy from keratin (Fig. 15-2, *A*).
- Nevoid basal cell carcinoma syndrome, an autosomal dominant condition associated with the *PTCH* gene (see Fig. 15-2, *B* and *C*), leads to multiple cystic lesions in the jaw; other findings include bifid rib, calcification of the falx cerebri, ovarian fibromas, palmar-plantar pitting, and medulloblastoma; this gene mutation is also seen in nonsyndromic keratocysts.

Histopathologic Features

- Epithelium is uniformly 5 to 10 cells thick, with parakeratosis, often revealing a corrugated surface and palisading of the basal cell nuclei with a flat interface, sometimes with mild basal cell hyperplasia (Fig. 15-3, *A* and *B*); keratinaceous debris fills the lumen; however, if inflammation is present, these typical features are lost or may be subtle or focal; focal areas may be covered by orthokeratin (Fig. 15-4).
- Satellite cysts may be present within the wall and sometimes within the mucosa if the cortical plate is perforated; this may indicate a higher recurrence rate and should be reported (Fig. 15-5).
- High PCNA and Ki-67 indices and positivity for p53 and p63 involving suprabasal cells is seen when compared with other odontogenic cysts (see Fig. 15-3, *C* and *D*).
- Cytokeratin (CK)17 and CK19 have been identified in the basal and suprabasal cells and CK4 and CK13 in superficial cells; CK10 is also present.
- Marsupialization of the cyst and flushing with a caustic agent results in loss of the parakeratin layer resulting in nondescript stratified squamous lining.

Differential Diagnosis

- Cysts lined entirely by orthokeratin do not exhibit palisaded basal cells and represent orthokeratinized odontogenic cysts with a low recurrence rate (see Chapter 14).
- Some basal cell hyperplasia is acceptable and, unless other features of atypia are present, should not be diagnosed as dysplasia.

Management and Prognosis

- Recurrence rate varies from 10% to 40%, depending on how the tumor is managed; when compared with en bloc resection, enucleation with application of Carnoy's solution, peripheral ostectomy with application of Carnoy's solution, and marsupialization followed by cystectomy do not show significant differences in recurrence rate; curettage is not recommended.

AMELOBLASTOMA

Central (intraosseous) ameloblastoma, the third most common odontogenic tumor next to keratocystic odontogenic tumor (odontogenic keratocyst) and odontoma, is a locally aggressive neoplasm, whereas the peripheral (extraosseous) ameloblastoma behaves in a benign fashion.

Clinical Findings

- Solid type: generally seen in the fourth to fifth decade; uniloculated or multiloculated radiolucency, most often in the posterior mandible, although blacks may have a predilection for lesions in the anterior mandible (Fig. 15-6, *A* and *B*); may cause swelling of the face if large; described as a solid tumor at surgery, although microcystic spaces may be present; the scirrhous or desmoplastic variant presents as a mixed lucent-opaque mass in 50% of cases (suggesting a fibro-osseous lesion) in adults in the fifth and sixth decades; equal mandibular and maxillary frequency, often affecting the anterior maxilla; some ameloblastomas are associated with impacted teeth (see Fig. 15-6, *C*).
- Unicystic or unicystic plexiform type: uniloculated radiolucency in the posterior mandible is often associated with an impacted tooth, usually in the second and third decades (see Fig. 15-6, *D*), described as cystic at surgery.
- Peripheral ameloblastoma occurs as a gingival nodule (see Chapter 5); rare cases occur at extragingival sites such as the buccal mucosa.

Histopathologic Features

Central ameloblastoma bears histologic and behavioral resemblance to basal cell carcinoma. They are classified by gross pattern and constituent cells.

- Solid ameloblastoma: *follicular type* shows islands of epithelial cells typically with peripheral basaloid cells showing reverse polarization of the nuclei; areas of cystic change within the epithelial islands are common; *plexiform type* shows anastomosing trabeculae and cords of epithelial cells with similar peripheral basaloid cell morphology, although this may be subtle (Figs. 15-7, *A-C* and 15-8).
- Variants are *classic* if the center of the islands show loose, stellate reticulum-like areas; *acanthomatous* if there are large, eosinophilic squamous cells or keratinization (Fig. 15-9; see Fig. 15-7, *D*); *granular cell* if cells with granular cytoplasm rich in lysosomes are present (Figs. 15-10 and 15-11); *keratoameloblastoma* if there is keratin production; and *basal cell*–type if basaloid cells predominate (uncommon type); classic and acanthomatous types are the most common and often coexist.
- Desmoplastic or scirrhous ameloblastoma is a variant of the follicular ameloblastoma, classic type, where islands of epithelium appear compressed by markedly desmoplastic stroma; tumors often show a combination of follicular and desmoplastic types (Fig. 15-12).
- Unicystic ameloblastoma: cyst lining is generally 5 to 15 cells thick and has the following features (Vickers-Gorlin criteria): palisaded basal cell nuclei with reverse polarization, stellate reticulum–like cells within the lining and eosinophilic (acanthomatous) luminal cells (Fig. 15-13); these changes are identical to those seen in cystic change within epithelial islands in solid ameloblastoma (see Fig. 15-9, *C*).
- Plexiform unicystic ameloblastoma is similar to the unicystic type, except that there is a plexiform proliferation of ameloblastomatous epithelium in an intraluminal or intramural pattern (Fig. 15-14, *A-C*); inflammation results in loss of the diagnostic features of this lesion and may lead to misdiagnosis of this cystic tumor as a radicular cyst or an inflamed nonspecific odontogenic cyst (see Fig. 15-14, *D* and *E*).

Differential Diagnosis

- Dentigerous cyst or other odontogenic cyst does not exhibit the Vickers-Gorlin criteria as noted; however, if the unicystic ameloblastoma is inflamed, these criteria may be lost.
- Squamous odontogenic tumor does not show palisading of the peripheral basal cells.
- Metastatic carcinoma is differentiated from desmoplastic ameloblastoma by the presence of frankly malignant cells consistent with the primary malignancy and lacks the palisading and reverse polarization of basal cells.
- Ameloblastic carcinoma shows obvious features of malignancy with hypercellularity, pleomorphic cells, many mitotic figures, and sometimes necrosis.

Management and Prognosis

- Solid lesions: recurrence rate is 17% if the tumor is resected and 35% if the tumor is curetted/enucleated; en bloc resection is the treatment of choice.
- For unicystic lesions, recurrence rates for those without and with mural proliferation are 6% and 37%, respectively; enucleation can be curative in many, but not all, cases, depending on the histopathology.
- Malignant transformation occurs in less than 1% of cases.

CALCIFYING EPITHELIAL ODONTOGENIC TUMOR (PINDBORG TUMOR)

Clinical Findings

- Occurs in adults in the third to fifth decade; appears as lucent or mixed radiolucent and radiopaque mass of the posterior mandible (70%) (Fig. 15-15, *A*); 60% are associated with an impacted tooth (Fig. 15-15, *B*); 5% to 6% are extraosseous; this tumor is locally aggressive and may perforate the cortical plate.

Histopathologic Features

This tumor recapitulates the stratum intermedium of the enamel organ.

- Cords, islands, and sometimes sheets of large, often polygonal cells with abundant eosinophilic cytoplasm are evident; variation in nuclear shape and size and pseudoinclusions are common, but mitotic activity is not seen unless malignant; congophilic amyloid-like material is always identified (Figs. 15-16 and 15-17); clear cells appear in 8% of tumors, although a variant contains predominantly clear cells.
- Variable amount of calcification occurs, in spite of the name, and this sometimes takes the form of concentric lamellar rings (Liesegang rings); calcifications are less commonly encountered in extraosseous forms; there is moderate fibrosis.
- Foci of this tumor are often seen within an adenomatoid odontogenic tumor.

Differential Diagnosis

- Malignant calcifying epithelial odontogenic tumor exhibits hypercellularity, hyperchromatic nuclei with coarse chromatin, and other features of malignancy.
- Metastatic carcinomas have significantly more atypia, mitotic activity, and desmoplasia.
- Primary clear cell odontogenic carcinoma does not produce amyloid and exhibits significant nuclear atypia.

Management and Prognosis

- Complete excision or enucleation is the treatment of choice; recurrence rate is up to 15%; clear cell variant may be more prone to occur.

ADENOMATOID ODONTOGENIC TUMOR

Clinical Findings

- Occurs in second decade of life with male predilection of 2:1; radiolucency and variable radiopacity present around the crown of impacted tooth (follicular type) (Fig. 15-18); two thirds of cases are in the maxilla, and two thirds are associated with the canine; extrafollicular tumors (not associated with a tooth) also occur, and extraosseous forms are rare.

Histopathologic Features

- Thickly encapsulated proliferation of nodules, whorls, and strands of spindled, columnar, and polygonal epithelial cells often with pale or clear cytoplasm; solid and reticular areas are present; ductlike structures and basophilic droplets of enameloid are characteristic, sometimes forming rosette-like structures (Figs. 15-19, *A-C* and 15-20, *A-C*); there is little fibrous stroma.
- Ductlike structures are CK19 positive and pseudolumina contain eosinophilic secretions or enameloid (see Figs. 15-19, *D* and *E* and 15-20, *D*); calcifications, some of which may be ringlike, may be seen (see Fig. 15-20, *E*); amyloid and calcifying epithelial odontogenic tumorlike areas are common (see later).
- Wall may have myxoid follicular tissue or be densely collagenized.

Management and Prognosis

- Excision is curative; recurrence rate is insignificant.

SQUAMOUS ODONTOGENIC TUMOR

Clinical Findings

- Third to fourth decade; well-demarcated radiolucency are equally distributed in the posterior mandible or anterior maxilla around the roots of teeth; one third are multicentric.

Histopathologic Features

- Irregularly shaped islands of mature squamous epithelium with dyskeratotic cells; some islands may exhibit cystic change or may contain eosinophilic amorphous secretions; fibrous stroma is abundant; unlke ameloblastoma, the peripheral cells are squamous or flattened cuboidal cells (Figs. 15-21 and 15-22).

Differential Diagnosis

- Follicular ameloblastoma, acanthomatous type, shows palisading of basal cell nuclei.
- Primary intraosseous and metastatic carcinomas show significant cytologic atypia.
- Squamous odontogenic-like proliferations composed of similar irregular islands of benign epithelium are sometimes seen in the walls of radicular cysts.

Management and Prognosis

- Enucleation, curettage, or excision is curative; recurrence is rare.

AMELOBLASTIC CARCINOMA

Ameloblastic carcinoma displays all the features of ameloblastoma, except that it has malignant cytology; metastatic ameloblastoma, a very rare condition, shows minimal cytologic atypia but has metastasized.

Clinical Findings

- Third to fifth decade; 2 : 1 male predilection; pain, mucosal ulceration and paresthesia often noted; more than two thirds occur in mandible, mostly posterior.

Histopathologic Features

The majority of ameloblastic carcinomas arise de novo; those that arise from preexisting ameloblastomas are considered secondary or dedifferentiated lesions.

- These tumors exhibit follicular (most common), plexiform, or trabecular pattern; infiltrative islands of tumor cells exhibit peripheral cell palisading, and reverse nuclear polarization with central stellate reticulum–like areas that are hypercellular; comedonecrosis, mitotic activity, and pleomorphic cells are present, and sometimes peripheral palisading is lost (Fig. 15-23); Ki-67 index is high; clear cells, ghost cells, and keratinization may be seen with focal dentinoid production (see Fig. 15-23).

Differential Diagnosis

- Primary intraosseous carcinoma and de novo ameloblastic carcinoma are likely related lesions, with the former showing less ameloblastic differentiation, in that basal cell palisading or formation of stellate reticulum–like areas is minimal or insignificant.
- Metastatic carcinoma must be ruled out.

Management and Prognosis

- En bloc resection with radiation or chemotherapy as appropriate results in 30% recurrence rate; 22% develop metastases, and half of those exhibit distant metastases to lungs, bone, and brain; 5-year survival with and without metastases is approximately 20% and 70%, respectively.

PRIMARY INTRAOSSEOUS SQUAMOUS CELL CARCINOMA

Clinical Features

- Occurs in the sixth and seventh decades; 2 to 3:1 male predilection; 80% posterior mandible, 10% anterior maxilla; poorly demarcated radiolucency of the mandible, often perforating cortex; pain, mobility of teeth, and paresthesia common.

Histopathologic Features

Tumors may arise de novo within the bone, from odontogenic cysts or odontogenic tumors (especially the keratocystic odontogenic tumor [odontogenic keratocyst]). Ameloblastic carcinoma is also a primary odontogenic carcinoma, albeit with characteristic features.

- Tumors present as infiltrative islands of squamous cells with minimal to moderate keratinization and may not be well differentiated; those arising from the lining of keratocystic odontogenic tumor (odontogenic keratocysts) are often keratinizing (Fig. 15-24); clear cells are present in 25% of cases, follicular pattern in 25%, and palisading peripheral cells in 8%; the lining of this tumor or other odontogenic cyst exhibits varying degrees of dysplasia; tumors may manifest as verrucous or papillary squamous carcinoma (Fig. 15-25).

Differential Diagnosis

- Ameloblastic carcinoma shows obvious palisading of the peripheral cells; differentiation between this and primary intraosseous carcinoma may be moot because both are primary carcinomas in bone of odontogenic epithelial origin.
- Primary squamous cell carcinoma of overlying the mucosa or from the maxillary sinus and metastatic squamous cell carcinoma must be ruled out.
- Mucoepidermoid carcinoma contains mucous cells and is not generally keratinizing; ductal structures may be present.
- Squamous odontogenic tumor exhibits benign histology and is not invasive and not keratinizing.

Management and Prognosis

- Resection is the treatment of choice, with adjuvant radiation therapy and chemotherapy as appropriate; recurrence rate is 20% to 60%; 10% develop distant

metastases to lungs, bones, and brain; one third of patients die of disease.

CLEAR CELL ODONTOGENIC CARCINOMA

Clinical Findings

- Sixth decade; 2:1 female predisposition; 75% occur in the mandible; pain, loosening of teeth, and paresthesia are often present, and it presents as a poorly demarcated radiolucency.

Histopathologic Features

- This is an infiltrative tumor that is composed of islands and lobules of round or polyhedral cells with well-defined borders and pale eosinophilic or clear cytoplasm, and small round-to-ovoid hyperchromatic nuclei with small nucleoli; atypia may be minimal, and mitoses may be present (Fig. 15-26); cells contain glycogen and are positive for cytokeratin (AE1/AE3, CK5/6, and CK19 among others) and EMA and are negative for S-100 protein and myoepithelial markers; stroma is fibrous; if the pale eosinophilic cells are more prominent, the term *biphasic* type is sometimes used; often, the peripheral cells exhibit subtle palisading of the basal cell nuclei, reminiscent of ameloblastoma.

Differential Diagnosis

- Clear cell calcifying epithelial odontogenic tumor has amyloid in the stroma.
- Clear cell mucoepidermoid carcinoma has mucous and epidermoid components, even if present focally.
- Clear cell variant of acinic cell adenocarcinoma has cells that contain periodic acid–Schiff (PAS)-positive, diastase-resistant zymogen granules.
- Clear cell adenocarcinoma of salivary gland origin may show glandular differentiation and is extremely uncommon as a primary intraosseous tumor.
- Epithelial-myoepithelial carcinoma is usually biphasic and contains myoepithelial cells.
- Metastatic renal cell carcinoma has nests of atypical clear cells that are CD10 and renal cell carcinoma antigen positive, with surrounding dilated vessels; other metastatic tumors can be ruled out with appropriate immunohistochemical stains and identification of primary site.

Management and Prognosis

- En bloc resection is the treatment of choice, and adjuvant radiotherapy is used for selected cases; there is a recurrence rate of 30% of resected and 87% of curetted/enucleated lesions; metastases are to lymph nodes, lung, and bones, and 25% of patients die of the disease.

Mixed Epithelial and Ectomesenchymal Tumors

CALCIFYING CYSTIC ODONTOGENIC TUMOR (CALCIFYING ODONTOGENIC CYST, GORLIN CYST) AND DENTINOGENIC GHOST CELL TUMOR

Clinical Features

- Fifty percent occur in the second and third decades; the cystic tumor manifests as a unilocular radiolucency (mixed lucency/opacity if associated with odontoma) usually of the anterior maxilla or the posterior mandible; tumor is often associated with an unerupted tooth (Fig. 15-27).
- Both the cystic tumor (85% of all cases) and dentinogenic ghost cell tumor (solid variant) also occur at peripheral (extraosseous) sites (see Chapter 15).

Histopathologic Features

The equivalent skin lesion is the calcifying epithelioma of Malherbe or pilomatrixoma. The following histologic subtypes are recognized:

- *Simple cystic:* single cyst lined by squamous or stellate reticulum–like cells with slight palisading of basal cells; ghost cells are present and exhibit eosinophilic cytoplasm, an empty space in place of the nucleus, and sometimes dystrophic calcifications; eosinophilic dentinoid is variably present and often juxtaepithelial (Fig. 15-28); melanin pigment is seen infrequently; lesions are often associated with an odontoma; the simple cystic and odontoma-associated lesions represent 65% and 22%, respectively, of all lesions; some cysts show significant proliferation of the cyst lining.
- *Ameloblastomatous*: in addition to simple cystic features, there is proliferation of ameloblastoma-like cords, islands, and sheets of epithelium with palisading of basal cell nuclei with reverse polarization within the wall (Fig. 15-29).
- *Dentinogenic ghost cell tumor*: similar components without a cystic structure; ghost cells are abundant, and there may be extensive dentinoid deposition and extensive calcifications (Fig. 15-30); some tumors may have areas resembling ameloblastoma.

Differential Diagnosis

- Ghost cell odontogenic carcinoma is infiltrative and exhibits mitotic activity, nuclear atypia, and/or necrosis. Lesions may arise de novo or from a preexisting cystic or solid tumor and sometimes from recurrent lesions.

Management and Prognosis

- Enucleation/excision is the treatment of choice; the cystic variant has a recurrence rate of 5%, and the solid variant of 17%; solid tumors should be treated with wider margins of excision.

AMELOBLASTIC FIBROMA

Clinical Findings

- Most common in the first and second decades of life, manifesting as swelling of the jaw: unilocular (sometimes multilocular) radiolucency usually in the mandible (75%); 90% found in the posterior aspects of the jaws (Fig. 15-31)

Histopathologic Features

Differentiation is toward ameloblastoma and dental papilla.

- Ameloblastoma with reverse polarization of basal cells and stellate reticulum–like areas is evident; in addition, there is a cellular proliferation of spindled and stellate fibroblast-like cells with dispersed nuclear

chromatin and small or inconspicuous nuclei in an extremely myxoid/mucinous background (Fig. 15-32).

- If dentinoid is present, the diagnosis is ameloblastic fibrodentinoma.

Differential Diagnosis

- Ameloblastic fibro-odontoma has identical soft tissue histopathology, but an odontoma is also present.
- Ameloblastic fibrosarcoma contains islands of benign epithelium typical for ameloblastoma, but there is a hypercellular proliferation of the spindle cells that show malignant morphology with hyperchromatic atypical nuclei, mitoses, and sometimes necrosis (Fig. 15-33); 44% of ameloblastic fibrosarcoma arise from preexisting ameloblastic fibroma and these occur in the fourth decade and later, whereas de novo ameloblastic fibrosarcoma occurs 1 decade earlier.

Management and Prognosis

- Excision or resection is the treatment of choice; recurrence is 33%; approximately 10% undergo malignant transformation to ameloblastic fibrosarcoma with younger presentation associated with increased risk; tumors do not tend to metastasize.

AMELOBLASTIC FIBRO-ODONTOMA

Some pathologists believe that ameloblastic fibro-odontoma and odontoma are a spectrum of the same condition, with odontoma being the more mature lesion; other pathologists consider them to be separate entities. There is no evidence at this time to suggest that one matures into the other.

Clinical Features

- Most cases (98%) occur in the first and second decades, with a mean age of 9 years; 54% occur in the posterior mandible, and 20% occur in the posterior maxilla; the most common presentation is a radiopacity overlying a tooth (often a permanent mandibular first molar), causing failure of eruption (Fig. 15-34).

Histopathologic Features

This tumor recapitulates the developing tooth with a prominent soft tissue component.

- Typical ameloblastic fibroma (Figs. 15-35, *A* and *B* and 15-36, *A* and *B*) with an odontoma; odontoma is usually of the complex type, consisting of haphazard deposition of tubular dentin, dentinoid, enamel matrix ("fish scale" appearance), cementum, ringlike calcifications, and odontogenic epithelium (see Figs. 15-35, *C-F* and 15-36, *C-F*).
- S-100 protein–positive, melanin-containing stromal cells may be present.

Differential Diagnosis

- Ameloblastic fibroma does not produce enamel, dentin, or cementum; ameloblastic fibrodentinoma produces dentinoid but not enamel matrix or tubular dentin.
- Odontoma has minimal soft tissue component and no ameloblastoma-like component.

Managment and Prognosis

- Enucleation or excision is curative.

ODONTOMA

This is the most common odontogenic tumor.

Clinical Features

- Lesion usually occurs in the second and third decades; complex odontomas are most common in the posterior mandible and anterior maxilla; compound odontomas are most common in the anterior maxilla; the mesiodens is a supernumerary or anomalous tooth located between maxillary central incisors.
- Radiopacity or radiopacities are visible with surrounding rim of radiolucency; recognizable tooth structures or denticles are present in compound odontomas; complex odontomas manifest as globular calcified masses (Fig. 15-37).

Histopathologic Features

Odontomas are considered hamartomas, and they recapitulate the development of a tooth, either in an organized (compound odontoma) or disorganized (complex odontoma) fashion.

- Compound odontoma: enamel matrix (basophilic fish-scale appearance), tubular dentin, cementum, and dental papilla (myxoid/mucinous material with stellate fibroblasts) present in the configuration of a tooth with varying amounts of odontogenic epithelium; the term *anomalous tooth* is sometimes used for a single, tooth-like structure (Fig. 15-38); a dental follicle surrounds the lesion.
- Complex odontoma is composed of dental hard tissues admixed with eosinophilic dentinoid, cementoosseous material, strands and islands of odontogenic epithelium, and dental papillae in haphazard fashion (Fig. 15-39); ghost cells (11% to 16% of cases), ringlike calcifications, enameloid, amyloid-like material, and ductlike structures may be present; rare cases contain melanin.
- Odontomas may be associated with other odontogenic lesions, in particular, calcifying cystic odontogenic tumor or adenomatoid odontogenic tumor.

Differential Diagnosis

- Ameloblastic fibro-odontoma has areas of ameloblastic fibroma.
- Ameloblastic odontoma (odontoameloblastoma) contains an odontoma and an area of typical ameloblastoma and may behave aggressively.

Management and Prognosis

- Excision is curative.

(Hybrid) Odontogenic Tumors

Some odontogenic tumors exhibit features of several different tumors. Common features are ameloblastic epithelium (basal palisading cells with stellate reticulum–like areas), nondescript odontogenic epithelium, ghost cells, ductlike structures similar to adenomatoid odontogenic tumor, deposition of dentinoid, cementum, or amyloid-like material, and ringlike calcifications. These structures may be organized into classifiable tumors such as calcifying epithelial odontogenic tumor or adenomatoid odontogenic tumor.

Mesenchymal Tumors

CENTRAL ODONTOGENIC FIBROMA

These lesions are classified as simple or epithelium-poor type (mostly fibrous tissue with little epithelium or dentinoid) and World Health Organization (WHO) classification or as complex or epithelium-rich type (epithelium invariably present, sometimes with dentinoid). Odontogenic fibroma devoid of epithelial rests is either very rare, if it exists at all, or represents dental follicle.

Clinical Features

- Occurs in fourth decade; unilocular radiolucency is present, usually in the mandible (Fig. 15-40); peripheral (extraosseous) counterpart is discussed in Chapter 5.

Histopathologic Features

Differentiation is toward dental follicle–like tissue.

- Proliferation of fibroblast-like spindle cells in a densely or delicately collagenized stroma; some tumors have a myxoid stroma; odontogenic epithelium may be sparse and often contains clear cells; hyaline globules (basement membrane–like material) or ductlike structures may be present (Fig. 15-41); eosinophilic material (dentinoid) may be present (Fig. 15-42); epithelium is positive for AE1/AE3, CK14, CK19, and other cytokeratins.
- Areas similar to central giant cell granuloma (see Chapter 16) are sometimes present.

Differential Diagnosis

- Cases that look similar to odontogenic fibroma occurring around the crowns of impacted teeth are almost always hyperplastic dental follicles.
- Odontogenic fibromyxoma, which tends to be epithelium poor and very myxoid, does not produce dentinoid.
- Desmoplastic fibroma is more densely collagenized and does not contain epithelium or dentinoid; it is often beta-catenin positive and behaves in a locally aggressive fashion.
- Metastatic carcinoma exhibits cytologic atypia and desmoplasia around epithelial islands.

Management and Prognosis

- Enucleation or curettage is the primary mode of treatment; recurrence rate is 4%; lesions associated with giant cell granuloma are particularly prone to recur (in up to 13% of cases).

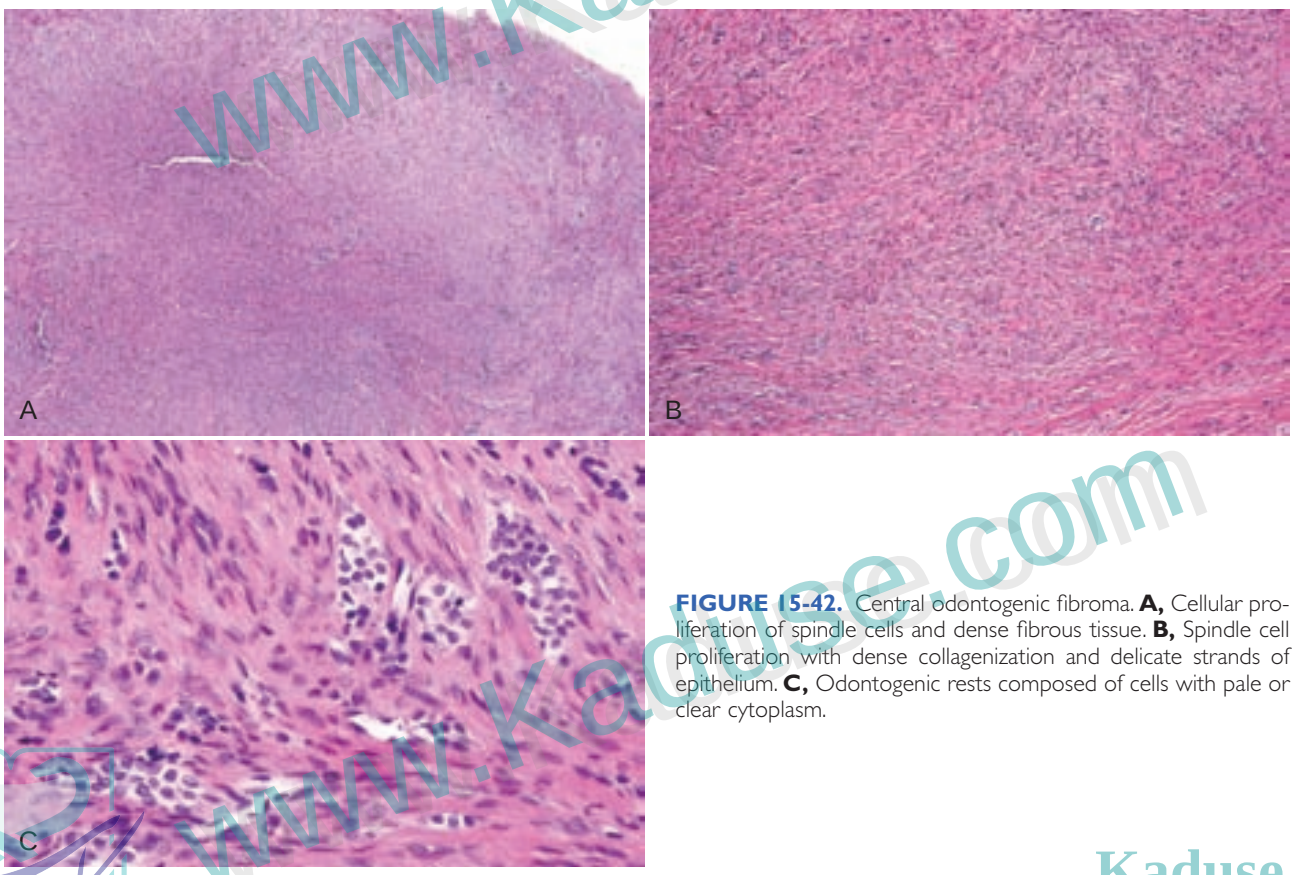

FIGURE 15-42. Central odontogenic fibroma. **A,** Cellular proliferation of spindle cells and dense fibrous tissue. **B,** Spindle cell proliferation with dense collagenization and delicate strands of epithelium. **C,** Odontogenic rests composed of cells with pale or clear cytoplasm.

ODONTOGENIC MYXOMA

Clinical Findings

- Occurs in second to fourth decade; often causing jaw bone expansion, with 2:1 female predilection; lesion is a poorly circumscribed, multilocular, or honeycombed radiolucency (60%), usually in the posterior maxilla or mandible; lesions are often associated with root resorption and perforation of the cortex; many are described as having a tennis racket appearance radiographically (Fig. 15-43).
- Mandibular lesions may involve the ramus extensively and maxillary lesions often involve the sinus.

Histopathologic Features

This tumor recapitulates the dental papilla.

- Unencapsulated and infiltrative proliferation of spindle, bipolar, and stellate cells with bland nuclei is present within a mucinous/myxoid stroma that contains abundant hyaluronic acid; islands of odontogenic epithelium are noted in less than 10% of cases, although they are revealed by AE1/AE3 and CK14 staining in 25% of cases (Fig. 15-44); perivascular hyalinization may be seen, usually with no calcified product formed, although there is one report of extensive calcifications.
- Spindle cells are S-100 negative; approximately 45% are SMA positive and up to 25% are HHF45 positive, suggesting the presence of myofibroblasts; mast cells are present in more than 70% of cases.

Differential Diagnosis

- Dental papilla (immature dental pulp from a developing tooth or odontoma) is often mistaken for myxoma; a rim of odontoblasts is present at the periphery of the dental papilla, which has an ovoid shape (Fig. 15-45).
- Intraosseous nerve sheath tumors are S-100 positive.
- Chondromyxoid fibromas contain chondroid areas, are less homogeneous with areas of cellularity, and are often multilobular.

Management and Prognosis

- Marginal resection is recommended for smaller tumors and segmental resection is recommended for larger tumors.
- Recurrence rate is up to 33%, depending on the mode of therapy.

GRANULAR CELL ODONTOGENIC TUMOR

Clinical Findings

- Occurs in the fifth to sixth decade; there is 3:1 female predilection; radiolucency in the mandible (75%) is usually posterior; rarely, lesions are peripheral (extraosseous).

Histopathologic Features

- Sheets and lobules of large, round cells with abundant eosinophilic, granular cytoplasm, eccentric round or ovoid nuclei with some variation in shape and size, and inconspicuous nucleoli; fibrovascular tissue is present between granular cells; islands of odontogenic epithelium do not exhibit palisading of basal cells, and clear cells may be present; cementum-like droplets are occassionally present (Figs. 15-46 and 15-47).
- Granular cells are S-100 protein negative and CD68 positive.

Differential Diagnosis

- Ameloblastoma, granular cell type, exhibits palisading and reverse nuclear polarization of basal cells.

Management and Prognosis

- Enucleation or curettage is the treatment of choice; recurrence is rare.

CEMENTOBLASTOMA

Clinical Findings

- Lesion occurs in second and third decades; mandible is two to three times more often affected than maxilla; more than 60% of patients report pain and/or swelling.
- Radiopaque mass (with surrounding lucent rim) is fused to the apex of a permanent tooth, usually mandibular first molar (50%); lamina dura is usually continuous around tooth and lesion; root resorption is often present (Fig. 15-48); some lesions are mixed lucent-opaque and infrequently, lucent only.
- Tooth may have been extracted and the root fractured, leaving behind a radiopaque mass in an edentulous area.

Histopathologic Features

Differentiation of tumor is toward cementoblasts, which deposit cementum; its bone-forming counterpart is osteoblastoma.

- Proliferation of cementoblasts (that appear similar to osteoblasts), which lay down cementum and woven bonelike material in masses and radiating columns, the latter best seen at the periphery; resting and reversal lines may be present, and root may be resorbed (Figs. 15-49, *A-C* and 15-50, *A-C*); cementoblasts are large with eccentric nuclei that may be slightly atypical, but contain dispersed chromatin and small nucleoli; osteoclast-like cells and dilated vessels may be seen (see Figs. 15-49, *D* and *E* and 15-50, *D* and *E*).

Differential Diagnosis

- Osteoblastoma does not have the same relationship with a tooth and, in particular, the peripheral radiating cementum seams.
- Cemento-osseous dysplasia in the early stage exhibits a cellular spindle cell population; it is sclerotic and dense in the later stage but does not exhibit the parallel cementum seams.
- Hypercementosis manifests as thickened cellular and acellular cementum attached to the tooth without proliferation of cementoblasts.

Management and Prognosis

- Excision or en bloc resection of the tumor with the tooth is the treatment of choice; recurrence rate is 20%.

16 Nonodontogenic Intraosseous Lesions

CHAPTER CONTENTS

TORI AND EXOSTOSES

Clinical Findings

- Tori: 2% to 10% of adults; exophytic, hard, uninodular or multinodular bony masses covered by mucosa that may be ulcerated from trauma; torus palatinus and torus mandibularis on the midline of palate and lingual mandible (usually bilateral and symmetric), respectively (Fig. 16-1, *A* and *B*); often site of bisphosphonate-associated osteonecrosis
- Exostoses: 27% of adults; male predilection (5:1); outgrowths of bone, nodular or sessile frequently on buccal aspects of mandible and maxilla or ascending arch of the palate and more than 90% having concurrent tori (see Fig. 16-1, *C* and *D*); exostoses possibly show rapid growth in some patients

Etiopathogenesis and Histopathologic Features

Tori and exostoses are likely developmental in nature, influenced by genetic and environmental factors with racial predisposition.

- Dense lamellar bone with well-spaced small osteocytes, fibrovascular tissue in haversian canals, variable osteoblastic rimming, especially if inflamed (Fig. 16-2); fatty marrow often present
- Long, sweeping collagen bundles (lamellae) noted under polarized light (Fig. 16-3)

Differential Diagnosis

- Dense bone island, bone scar, or idiopathic osteosclerosis is not exophytic and is an asymptomatic intraosseous radiopacity not related to teeth that is discovered

on routine radiography (Fig. 16-4, *A*); biopsy is not necessary unless the lesion is radiographically progressive; histopathology is similar and bone is often sclerotic.

- Condensing osteitis is similar to idiopathic osteosclerosis but is found at or very close to the apices of teeth and is likely reactive to chronic occlusal trauma or low-grade inflammation or odontogenic infection; biopsy is not necessary (see Fig. 16-4, *B*).
- True osteomas are associated with Gardner syndrome (autosomal dominant condition associated with mutation in the APC gene and development of colonic polyps and carcinoma, desmoid tumors, supernumerary teeth, and skin cysts).

Management and Prognosis

- Excision is performed usually because patient wants a denture made, or if lesion is constantly ulcerated from trauma.

FIBRO-OSSEOUS LESIONS

Fibro-osseous lesions are a heterogeneous group of lesions composed of osseous dysplasias, inflammatory conditions, and neoplasms, characterized by a proliferation of fibroblast-like cells and deposition of osseous or cementum-like material. Their histologic features overlap, depending on the stage in which the biopsies are obtained, and an accurate diagnosis can be rendered only after correlation of clinical and radiographic data. Differentiation between lesions is essential so that appropriate therapy can be instituted. The lesions considered here are fibrous dysplasia, cemento-osseous dysplasia, cemento-ossifying fibroma, aggressive ossifying fibroma, and familial gigantiform cementoma. Nomenclature for these lesions continues to evolve.

Clinical Findings

- Please see Table 16-1 and Figs. 16-5 to 16-10.

Etiopathogenesis and Histopathologic Features

Fibrous dysplasia is associated with a mutation in the GNAS gene that results in alterations in proliferation and differentiation of preosteoblasts; there are monostotic (85% to 90% of cases) and polyostotic types; the latter is seen in McCune-Albright syndrome and is often associated with endocrinopathies and skin pigmentation. The other conditions have not been shown to be consistently associated with gene mutations, although familial gigantiform cementoma is an inherited disorder.

- *Fibrous dysplasia* consists of a proliferation of benign fibrous tissue and either small, delicate, or curvilinear trabeculae of woven bone in early lesions, or thicker and denser trabeculae of woven or lamellar bone in mature lesions; osteoblastic rimming and occasional osteoclasts may be seen focally, especially in early and inflamed lesions; there is variable vascularity (Figs. 16-11 and 16-12); aneurysmal bone cyst–like areas may be seen.
- *Cemento-osseous dysplasia* consists of a cellular proliferation of spindled benign fibroblast-like cells and deposition of osteoid, woven bone, cementum droplets, or a mixture thereof; mature lesions consist of a mass of cementum that has a rounded, globular appearance with few cementocytes (sclerotic cemental mass) (Figs. 16-13 to 16-15); cells that rim bone and cementum are often osteoblast-like.
- *Cemento-ossifying fibroma* consists of cellular proliferation of spindled fibroblast-like cells that deposit osteoid, trabeculae of woven bone, and cementum droplets in varying proportions; osteoblastic rimming is common (Fig. 16-16).

TABLE 16-1 Clinical Findings in Benign Fibro-osseous Lesions

Condition	Age	Site	Radiographic Appearance
Fibrous dysplasia	Second and third decades with painless expansion of bone and swelling of midface; older patients with persistent mature lesions; pregnancy may cause exacerbation	>90% of cases monostotic; unilateral affecting maxilla and often maxillary sinus and contiguous facial bones; sometimes with displacement of orbital floor; less common in the mandible	Diffuse ground-glass appearance of bone that merges with normal bone (see Fig. 16-5); loss of lamina dura; if in mandible, inferior alveolar canal may be displaced if long-standing
Focal cemento-osseous dysplasia	Occurs in white or black females in fourth to fifth decade; no swelling	Apex of vital tooth, usually mandibular first or second molar	Periapical radiolucency with increasing opacities as it matures; sclerotic rim in continuity with lamina dura (see Fig. 16-6, *A*)
Variant: periapical cemento-osseous dysplasia	Usually occurs in black females in fourth to fifth decade; no swelling	Apices of anterior mandibular incisors or canines; teeth vital	Same as above (see Fig. 16-6, *B*)
Mutlifocal (florid) cemento-osseous dysplasia	Usually occurs in black females in fourth to fifth decade; may develop swelling if simple bone cysts occur	Apices of vital teeth in multiple quadrants	Same as focal cemento-osseous dysplasia involving multiple teeth (see Fig. 16-7); simple bone cysts occur in long-standing lesions
Cemento-ossifying fibroma	Adults with increasing swelling of the face	60% to 70% occur in the body of the mandible	Well-demarcated radiolucency usually unassociated with teeth with variable radiopacities (see Fig. 16-8)
Aggressive (juvenile) ossifying fibroma	Usually occurs in first and second decade with psammomatoid type in slightly younger patients; rapidly developing facial swelling	Psammomatoid type affects maxilla and bones of paranasal sinuses Trabecular type affects maxilla and mandible equally	Usually fairly large radiolucency, generally well-demarcated with variable radiopacities sometimes with destruction of cortical plates (see Fig. 16-9)
Familial gigantiform cementoma	Autosomal dominant or sporadic; arises in childhood causing severe facial deformity by adulthood; some lesions do not cause jaw expansion	Involves at least two quadrants and usually all four	Expansile radiolucency with radiopacities (see Fig. 16-10)

- *Aggressive ossifying fibroma (desmo-osteoblastoma)* consists of a cellular proliferation of plump and stellate fibroblast-like cells with large, slightly atypical nuclei, clusters of multinucleated giant cells, and fresh hemorrhage; trabecular variant has abundant woven bone surrounding large osteocytes with many osteoblasts (Figs. 16-17 and 16-18); psammommatoid variant has many basophilic cementum droplets or psammomatoid bodies, most of which are of uniform size (Fig. 16-19); this subtype appears similar to familial gigantiform cementoma.
- *Familial gigantiform cementoma* is similar to ossifying fibroma, especially psammomatoid type.

Differential Diagnosis

- Cementoblastoma shows a proliferation of cementoblasts (resembling osteoblasts) with radiating seams of cementum (see Chapter 15).
- Osteoblastoma shows a proliferation of osteoblasts composed of large cells with eccentric nuclei, often multilayered against the bone, osteoclasts on the same trabeculae, and prominent ectatic vessels (Fig. 16-20); bone is basoophilic, sometimes with many resting and reversal lines.
- Renal osteodystrophy from secondary hyperparathyroidism may manifest with similar histology to fibrous dysplasia; clinical features of renal failure with hypercalcemia differentiate the two.

Management and Prognosis

- Fibrous dysplasia: recontouring is for aesthetics only.
- Cemento-osseous dysplasia: no treatment necessary; however, sclerotic masses of cementum are hypovascular and extractions may lead to osteomyelitis; simple bone cysts are associated with long-standing lesions (Fig. 16-21).
- Cemento-ossifying fibroma: curettage, enucleation, or excision is curative.
- Aggressive ossifying fibroma: wide excision is the treatment of choice; recurrence is 30% to 50%, primarily because of incomplete excision.

PAGET DISEASE OF BONE (OSTEITIS DEFORMANS)

Paget disease of bone is a metabolic bone disease that leads to disorganized deposition of bone that is dense but has poor mechanical strength and, therefore, is prone to fractures.

Clinical Findings

- Affects 1% to 2% of the white population (usually men) older than age 55, with highest frequency in the United Kingdom and lowest frequency in Asia; familial history in 15% to 40% of cases; first sign may be bone pain and headaches; deposition of bone around skull foramina may lead to neurologic symptoms, such as hearing or visual loss; poor fit of dentures or hats and spacing between teeth may occur from expansion of skull and jaw bones.
- Radiographs in early stages show osteoporotic changes; in the mixed stage, there is thickening of bones with mixed radiolucency and radiopacity ("cotton wool appearance") with bone sclerosis being more marked as disease progresses (Fig. 16-22).
- High levels of bone-specific alkaline phosphatase and urine hydroxyproline are noted.

Etiopathogenesis and Histopathologic Findings

Both genetic and environmental influences have been identified. Some cases are inherited in an autosomal dominant fashion; sequestosome, a gene that encodes p62 (a protein involved in NFκB signaling) is present in 20% to 50% of inherited and 5% to 20% of sporadic cases; increased number and activity of osteoclasts leads to initial resorption of bone and osteoporotic appearance (osteoclastic stage), followed by compensatory but overproduction of lamellar bone in a haphazard fashion with prominent vascularity (mixed osteoclastic-osteoblastic stage), and finally, "burnt out" stage with fibrosis of connective tissue; the role of paramyxovirus and other viruses (such as measles and distemper virus) as a trigger is controversial.

- The haphazard deposition of bone results in a mosaic pattern and many resting and reversal lines; numerous giant, irregular-shaped, hypernucleated osteoclasts are present; many osteoblasts are noted on surface of bone trabeculae, and there is marked hypervascularity in the mixed stage (Fig. 16-23).
- Giant cell tumors occur infrequently in association with this disease.
- Microtubular inclusions are seen on ultrastructural studies.

Differential Diagnosis

- Osteoblastoma may look similar with many osteoclasts (although these are not usually hypernucleated), osteoblasts, and hypervascular stroma, but radiographs show a diffuse process in Paget disease.

Management and Prognosis

- Treatment is with antiresorptive drugs, such as bisphosphonates (first line of treatment), or calcitonin; antiinflammatory agents for management of pain, and surgery for correction of deformities.
- Less than 1% of cases develop osteosarcoma (usually osteoblastic type).

CENTRAL GIANT CELL GRANULOMA (AGGRESSIVE AND NONAGGRESSIVE GIANT CELL LESION, CENTRAL GIANT CELL LESION, CENTRAL GIANT CELL REPARATIVE GRANULOMA)

Data suggest that the nonaggressive and aggressive giant cell granulomas and lesions of the maxillofacial complex have similar clinical presentations and treatment outcomes when compared, respectively, with the nonaggressive and aggressive axial-appendicular giant cell lesions; therefore, they may represent the same disease process.

Clinical Findings

- Lesions occur in the first to third decade of life, often presenting as a unilocular or multilocular radiolucency of the mandible (75% of cases), usually in the anterior or body (Fig. 16-24, *A*).
- Aggressive type is less than 5 cm, recurs (primary criteria) or shows at least three of the following secondary criteria: rapid growth, root resorption, tooth displacement and thinning, or perforation of the cortical plate (see Fig. 16-24, *B*).
- Multiple giant cell lesions are often seen in Noonan-like multiple giant cell lesion syndrome (associated with *PTPN11* and *SOS1* mutations, among others) and in hyperparathyroidism.

Etiopathogenesis and Histopathologic Features

Cells are derived from mesenchymal stromal cells that differentiate along the monocyte-macrophage-osteoclast lineage. No consistent genetic abnormalities have been noted, although frequent telomeric associations have been reported in giant cell tumor of bone.

- Proliferation of mononuclear cells and clusters of multinucleated osteoclast-like giant cells with abundant fresh hemorrhage, siderophages, and reactive osteoid and woven bone formation; giant cells have 20 to 30 nuclei; mononuclear cells often show mitotic activity (Figs. 16-25 and 16-26).
- More extensive vasculature may correlate with aggressive lesions.
- Most giant cells and approximately 10% of mononuclear cells stain for tartrate-resistant acid phosphatase, CD68, cathepsin, and MMP-9; in situ hybridization studies show mRNA for osteoprotegrin within giant cells and RANK and RANKL within stromal cells; both show variable staining for glucocorticoid and calcitonin receptors.

Differential Diagnosis

- Brown tumor of hyperparathyroidism is indistinguishable from central giant cell granuloma; high parathormone levels and serum calcium differentiate the two conditions.
- Giant cell tumors of bone tend to have sheets rather than clusters of giant cells, which contain more nuclei, although distinction may be difficult; differences in histopathology may predict more aggressive behavior.
- Aneurysmal bone cyst consists of large blood-filled spaces lined by giant cells.
- Cherubism is distinguished by its typical bilateral presentation.
- Abundant woven bone deposition may suggest a fibro-osseous lesion, but giant cells usually are not a feature in the latter.

Management and Prognosis

- Recurrence in 10% to 70% of cases depending on mode of therapy.
- Curettage, excision, resection, intralesional steroid injections, calcitonin nasal spray; enucleation and/or tumor debulking with adjuvant interferon-α therapy have been successful in resolving lesions completely (Fig. 16-27).
- Other treatment modalities are bisphosphonate and imatinib therapy.

CHERUBISM

Clinical Findings

- Condition occurs most frequently in first decade; bilateral multiloculated radiolucencies of the posterior mandible and ascending ramus often result in tooth displacement, delayed tooth eruption, and loosening of teeth (Fig. 16-28); involvement of the maxilla causes eyes to turn upward, resembling a cherub; a unilateral lesion may be the first presentation.
- Lesions cause bony expansion and swelling up to age 12; symptoms are usually quiescent for a few years and then regress over many years beginning in adolescence.

Etiopathogenesis and Histopathologic Features

Cherubism is an autosomal dominant condition caused in many, but not all, cases by a mutation in the *SH3BP2* gene on chromosome 4p16.3 that encodes c-Abl-binding protein; tumor necrosis factor may mediate bone loss.

- Clusters of multinucleated osteoclast-like giant cells and proliferation of spindled and mononuclear cells are present in a delicately fibrous stroma; foci of hemorrhage and perivascular hyalinization are common (Fig. 16-29).

Differential Diagnosis

- Central giant cell granuloma generally has more giant cells and, importantly, is a solitary lesion in the anterior and body of mandible.
- Noonan syndrome (characterized by short stature, cardiac defects, chest deformity, and facial dysmorphism such as hypertelorism, downward slanting palpebral fissures, and low-set, posteriorly placed ears) is associated with mutations in *PTPN11* gene in 50% of cases; Noonan-like multiple giant cell lesion syndrome shows overlap with Noonan syndrome but also presents with giant cell lesions, and some have mutations in the *PTPN11* or *SOS1* gene.
- Aneurysmal bone cyst has blood-filled spaces rimmed by giant cells.

Management and Prognosis

- Recontouring of the bone is for aesthetics only; rare cases respond to calcitonin and most symptoms regress.

DESMOPLASTIC FIBROMA

This lesion is an intraosseous counterpart of desmoid-type fibromatosis (aggressive fibromatosis or extraabdominal desmoid).

Clinical Findings

- Lesion occurs in 85% of patients who are younger than 30 years; 85% of lesions are in mandible; jaw swelling occurs, sometimes with pain; well-defined radiolucency with cortical perforation and extension into soft tissues is seen in 30% of cases.

Etiopathogenesis and Histopathologic Features

Lesion likely arises from mesenchymal stem cells within bone and in rare cases demonstrate trisomy 8 and 20. The absence of involvement of APC–β-catenin pathway suggests that, although it morphologically resembles desmoid-type fibromatosis, it develops via a different tumorigenic pathway.

- Proliferation of spindled fibroblasts and myofibroblasts in a richly collagenized stroma with sweeping fascicles and variable hyalinization; relatively paucicellular, minimal to no cytologic atypia, and mitoses may be present (Fig. 16-30); positive for smooth muscle actin in more than 50% of cases; occasionally desmin positive
- β-catenin positive in cytoplasm in up to 50% of cases, but nuclear staining rare

Differential Diagnosis

- Benign fibrous histiocytoma has a whorled, storiform pattern with histiocytes and multinucleated giant cells.
- Muscle tumors are more cellular, and cells have abundant eosinophilic cytoplasm; neural tumors are positive for neural markers.

Management and Prognosis

- Excision with clear margins is treatment of choice, with 5% recurrence; curettage results in 30% recurrence.

OSTEOSARCOMA (OSTEOGENIC SARCOMA)

Osteosarcoma is the most common primary non-hematopoietic malignancy of bone and the second most common intraosseous malignancy after multiple myeloma. There are two forms: intramedullary and surface-juxtacortical. In general, intramedullary gnathic osteosarcomas occur 10 to 20 years later than long bone osteosarcoma, and they tend to be medium- or high-grade tumors.

Clinical Findings

- Lesion occurs in the third to fourth decade with pain, swelling, and paresthesia; equally distributed in mandible and maxilla; lesion may erode bone to involve soft tissues; mixed lucent-opaque lesion appears with poorly defined borders (Fig. 16-31, *A*); intraoral periapical radiographs show widening of periodontal ligament space; parosteal osteosarcomas are enlarging masses attached to surface of the jaw bones (see Fig. 16-31, *B*); a sun burst-like osteophytic reaction is seen on radiographs if the periosteum is involved.

Etiopathogenesis and Histopathologic Features

Chromosomal aberrations involving chromosomes 1, 11, 14, 15, 17, and 19 have been noted in osteosarcoma of long bones. Secondary osteosarcoma may develop in preexisting Paget disease of bone or with a history of radiation. Patients who develop osteosarcoma with a history of hereditary retinoblastoma or Li-Fraumeni syndrome with mutations in RB1 tumor suppressor gene and TP53 gene, respectively, have poorer prognosis.

Intramedullary lesions are usually chondroblastic, osteoblastic, or fibroblastic (least common); giant cell,

small cell, telangiectatic, and dedifferentiated types are rare; pediatric cases may be primarily osteoblastic; up to 80% are high-grade tumors.

- Atypical osteoblasts lay down irregular, lacy, basophilic trabeculae of malignant osteoid and woven bone; cells have large nuclei and nucleoli that are hyperchromatic (Fig. 16-32); atypical cartilage formation is seen in the chondroblastic type, and the fibroblastic type contains atypical spindle cells (Fig. 16-33).
- Parosteal (low-grade juxtacortical) osteosarcoma is a low-grade osteosarcoma that is easily mistaken for a benign fibro-osseous lesion; thick anastomosing trabeculae of bone are surrounded by fibrous tissue with minimal atypia; very focal osteoblastic rimming is present, and there is infiltration of the cortex; 25% to 50% show cartilage formation with ossification (Figs. 16-34 and 16-35); dedifferentiation occurs in 15% to 20% of cases, and this is associated with a poorer prognosis; MDM2 and CKD4 positivity has been noted in more than 80% of cases.
- Intramedullary low-grade osteosarcoma lesions also show spindle cell proliferation with deposition of osteoid or cementum-like material; dedifferentiation occurs in long bone tumors.
- Periosteal osteosarcoma is chondroblastic osteosarcoma of intermediate grade.
- High-grade juxtacortical osteosarcoma reveals cells that are more atypical, and chondroblastic types are difficult to differentiate from periosteal osteosarcoma.

Differential Diagnosis

- Osteoblasts in osteoblastoma are less atypical, and bone trabeculae are more regular in contour and more uniform overall; prominent vasculature and osteoclasts are noted; histopathologic differentiation between the two may be difficult, but osteoblastoma presents as a circumscribed lucent-opaque lesion.
- Aggressive ossifying fibroma may show atypical osteoblasts but overall is fairly uniform in appearance and malignant bone is not formed.
- Fibrous dysplasia does not show significant atypia, and it may be difficult to distinguish from low-grade fibrous dysplasia–like osteosarcoma; however, the latter is often CDK4 and MDM2 positive.
- Chondrosarcoma does not usually produce malignant osteoid, although lesions may calcify.

Management and Prognosis

- Surgery and adjuvant chemotherapy is the treatment of choice; 5-year survival is 60%, and recurrence rate is 40% with 17% distant metastases.
- Prognosis is worsened with high histologic grade, involvement of margins, recurrence, advanced age, and in secondary osteosarcomas; in the long bones, long-term survival is 80% to 90% versus 15% for those who respond (>90% necrosis in tumor) to those who do not respond (<90% necrosis) to preoperative therapy.
- Parosteal osteosarcoma has better prognosis, with 90% 5-year survival; dedifferentiation is associated with a higher rate of metastasis, especially to the lungs.

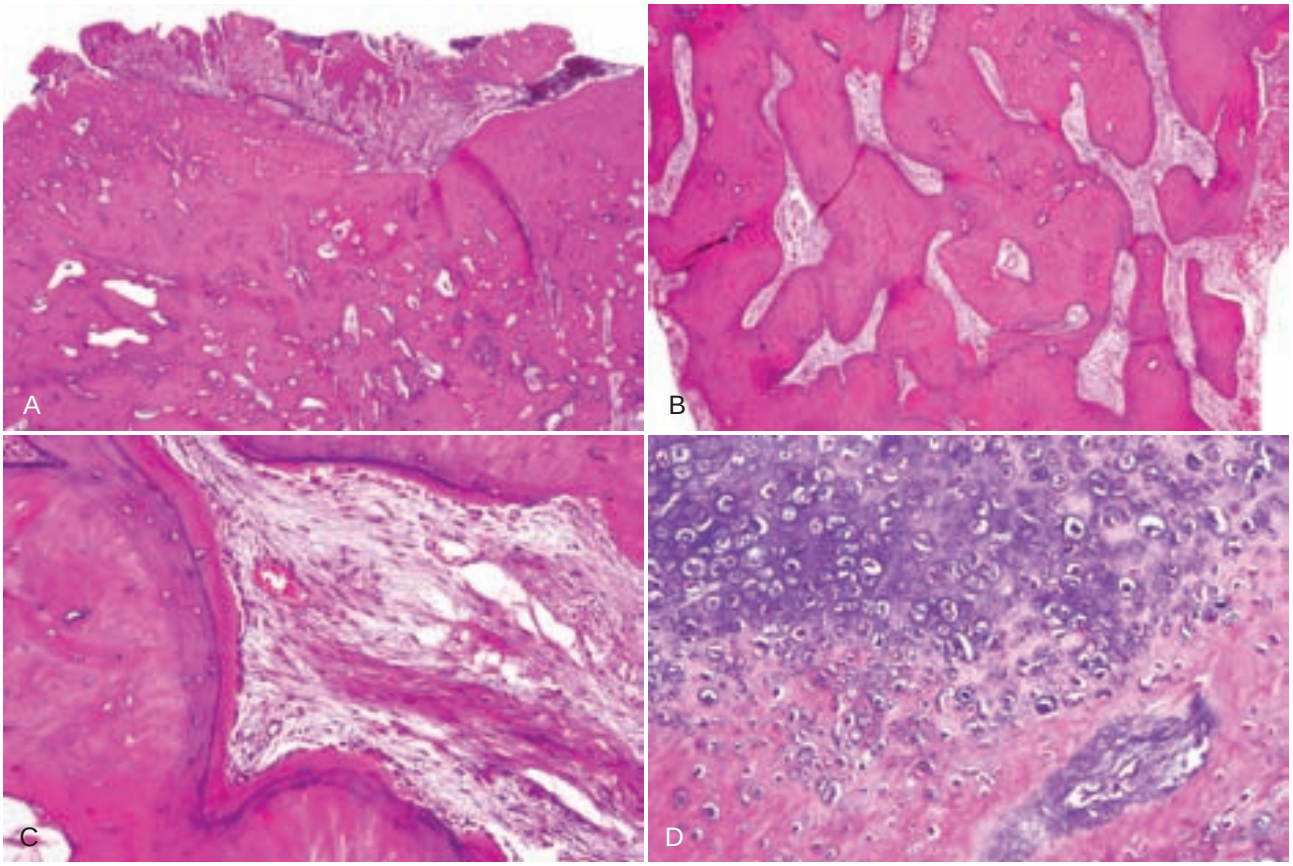

FIGURE 16-35. Low-grade parosteal osteosarcoma. **A,** Sclerotic mass of atypical bone lying in the lamina propria, completely replacing the normal cortex. **B,** Anastomosing seams of bone with intervening relatively hypocellular fibrovascular tissue. **C,** Bone rimmed by a single layer of bland-appearing osteoblasts with bland spindle cells in the stroma. **D,** Focal area of cartilaginous differentiation.

CHONDROSARCOMA

Cartilaginous tumors within the jaw bones should be considered chondrosarcomas until proved otherwise because benign intraosseous chondroid tumors are extremely rare; in soft tissues, cartilaginous rests may be found in the nasopalatine area, within denture-related fibrous hyperplasia (epulis fissuratum), and within other neoplasms such as lipomas and pleomorphic adenomas.

Clinical Findings

- Conventional chondrosarcoma: fifth and sixth decade; pain and swelling of the jaw; poorly demarcated destructive radiolucency with most cases showing coarse calcifications (Fig. 16-36)
- Mesenchymal chondrosarcoma: frequent in second decade; one third extraosseous; rib and jaw bones being two common sites
- Twenty-five percent to 30% of patients with Ollier disease (enchondromatosis) and Mafucci syndrome (enchondromatosis and vascular lesions) develop chondrosarcoma

Etiopathogenesis and Histopathologic Features

Conventional chondrosarcoma may show amplification of 12q13 and loss of 9p21; identical robertsonian translocation der(13;21)(q10;q10) has been identified in some cases of mesenchymal chondrosarcoma.

- *Conventional chondrosarcoma*: proliferation of atypical chondrocytes and cartilage that permeate medullary spaces; chondrocytic atypia takes the form of binucleation and multinucleation, nuclear pleomorphism and hyperchromatism, and more than one chondrocyte within a lacuna; dystrophic ossification is a common finding, but there is no deposition of malignant osteoid or woven bone (Fig. 16-37); chondroblasts are SOX9 and podoplanin (D2-40) positive; graded 1 (least atypia) to 3 (markedly pleomorphic cells often with necrosis and mitoses); grade 1 and combined grades 2 and 3 tumors have a recurrence rate of 89% and 53%, respectively; CD44 more highly expressed in higher grade tumors and associated with poorer prognosis
- Clear cell, dedifferentiated, and periosteal variants

- *Mesenchymal chondrosarcoma*: biphasic pattern of recognizable cartilage and proliferation of small, darkly staining round cells; chondrocytes within cartilage exhibit atypia; small round cells with distinct cytoplasmic outlines, scant cytoplasm (sometimes clear), and hyperchromatic round-to-ovoid nuclei arranged in nests with surrounding dilated vessels (hemangiopericytoma pattern) or solid sheets (Fig. 16-38), dystrophic calcifications are noted, but no malignant bone produced.
- Cells are CD99 positive, S-100 protein positive only in the chondroid areas, and SOX9 positive in both areas; EMA negative; type II collagen is a sensitive marker for this tumor.

Differential Diagnosis

- Chondroblastic osteosarcoma (intramedullary and periosteal types) produces malignant woven bone and osteoid and not just dystrophic calcifications.
- Presence of cartilage (may need serial sections to locate) in mesenchymal chondrosarcoma rules out other small round cell tumors such as lymphoma, rhabdomyosarcoma, Ewing sarcoma, neuroblastoma, and malignant solitary fibrous tumor, as does presence of type II collagen
- Chordoid chordoma is cytokeratin and EMA positive and podoplanin (D2-40) negative.

Management and Prognosis

- Wide en bloc resection with or without adjuvant radiotherapy and chemotherapy is recommended treatment.
- Recurrence rate is 30% to 40%, with metastases often to lungs and death from disease.
- Five-year survival is approximately 85% for juxtacortical, 75% for conventional, 70% for myxoid, and 50% for mesenchymal subtypes.

PLASMA CELL MYELOMA (MULTIPLE MYELOMA)

Plasma cell myeloma is the most common intraosseous malignancy, and variants include solitary plasmacytoma, extramedullary plasmacytoma, nonsecretory myeloma, indolent myeloma, smoldering myeloma, monoclonal gammopathy of unknown significance, and plasma cell leukemia.

Clinical Findings

- Occurs in sixth and seventh decades and is twice as common in females and is more common in blacks; the lesion seldom occurs in the jaw without other bones being involved; disease causes bone pain, hypercalcemia, fractures, and anemia from renal involvement.
- Lytic, punched-out lesions occur in the jawbones and calvaria (Fig. 16-39, *A*); extension into soft tissue forms fleshy masses (see Fig. 16-39, *B* and *C*); patients may present with waxy, yellowish, firm amyloid nodules, especially of the tongue (see Fig. 16-39, *D*).
- M-component in peripheral blood and urine is present in 99% of cases; 50% are IgG, 20% to 25% IgA; monoclonal light chain (Bence Jones protein) is found in serum or urine in 75% of cases.

Etiopathogenesis and Histopathologic Features

Plasma cell myeloma is a malignant clonal proliferation of plasma cells. Disease occurring in POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes) syndrome are associated with human herpesvirus type 8.

- Sheets of plasma cells are present, with many dilated vessels; plasma cells, if well differentiated, these have abundant amphophilic cytoplasm, eccentric nuclei, clumped chromatin against the nuclear membrane (clock face appearance) and perinuclear zone of Hopf (Golgi apparatus) (Fig. 16-40); Russell bodies (eosinophilic bodies filled with immunoglobulin) may be noted, nuclear atypia may be significant, and there may be Dutcher bodies (PAS-positive nuclear pseudoinclusions).
- Cells are positive for CD38, CD138, and CD79a, with light chain restriction (see Fig. 16-40, *C* and *D*); they are usually CD20 and CD45 negative and may be positive for CD56.

Differential Diagnosis

- Oral plasmablastic lymphoma (mostly in HIV-positive patients) usually manifests on the gingiva or palate (typical for other oral lymphomas) and sometimes in the jawbones; there is no immunoglobulin spike; tingeable body macrophages lead to a starry-sky appearance; cells have moderate cytoplasm, large eccentric nuclei, prominent central or peripheral nucleoli, with similar profile to plasma cells being CD138, MUM1, and CD38, positive and CD20 negative (Fig. 16-41); mitotic activity is frequent, and tumors have a high K1-67 index; the majority of cases are Epstein-Barr virus (EBV)–encoded RNA positive; oral plasmablastic lymphomas associated with HIV infection have a different immunoprofile from extraoral lesions that are not HIV associated.
- Non-Hodgkin lymphoma (>90% B cell) occurs in jaw bones in 30% to 50% of cases; usually large, diffuse B-cell type (60% to 70%) and are CD20 positive (Figs. 16-42 and 16-43); 60% show IgH gene rearrangement and 20% show Bcl-2 translocation; those that exhibit germinal center markers (CD10 and Bcl6) have a better prognosis.
- Ewing sarcoma consists of sheets of small, round cells, sometimes with clear cytoplasm (containing glycogen) and delicate, granular chromatin, that are CD99 positive; characterized by reciprocal translocation t(11:22)(q24;q12) involving the *EWS* gene on chromosome 22 and the *FLI-1* gene on chromosome 11; median age is in the second decade (Figs. 16-44 and 16-45).

Management and Prognosis

- Treatment for plasma cell myeloma is chemotherapy, bisphosphonates, thalidomide and related drugs, corticosteroids, bortezomib, radiation, and stem cell transplantation.
- Median survival is 3 years; 10% of patients have a 10-year survival.

LANGERHANS CELL HISTIOCYTOSIS

This disease ranges from a single lesion that may regress to severe multisystem involvement that may be fatal. Approximately 60% to 70% of patients have restricted single-system disease (unifocal or multifocal, often with diabetes insipidus) and the rest have multisystem disease that may be low risk without organ dysfunction or high risk with organ dysfunction. Single-system and multisystem disease is most commonly seen in children, with single-system pulmonary disease affecting adults in the third and fourth decades. Primary involvement of bone, skin, and lymph nodes, occurring unifocally or multifocally, is often seen in restricted single-system disease.

Clinical Findings

- Disease occurs in first and second decades; jaws are the third most commonly affected site after the skull and the femur; there is loosening of teeth locally; radiograph may show nondescript periapical radiolucency or floating teeth because of severe bone loss (Fig. 16-46); rarely, lesions are in soft tissue only.

Etiopathogenesis and Histopathologic Features

This is a tumor of Langerhans cells, an antigen-presenting cell. Some lesions are clonal or caused by dysregulation of Langerhans cells, whereas those that occur in the lung in adults associated with smoking may be reactive.

- Sheets of epithelioid histiocyte-like cells are present with abundant, pale eosinophilic cytoplasm and grooved or reniform ("coffee bean") nuclei; many eosinophils are present (Fig. 16-47, *A-C*); T cells, macrophages, and multinucleated giant cells are often seen.
- Cells are positive for CD1a, CD207 (langerin), and S-100 protein; Birbeck granules (tennis racket–shaped bodies) are a typical ultrastructural finding, and they form after ligand-binding to langerin (see Fig. 16-47, *D* and *E*).

Differential Diagnosis

- Traumatic ulcerative granuloma (eosinophilic granuloma of tongue) does not significantly stain for Langerhans cells.
- Nonspecific macrophage-dense infiltrates in periapical lesions do not usually contain eosinophils and do not stain for Langerhans cells.

Management and Prognosis

- Curettage is often curative; other treatments include indomethacin (bone lesions often PGE2 positive), bisphosphonates and chemotherapy (prednisone and vinblastine); reactivation occurs in 25% of patients with multifocal bone disease and is correlated with the presence of diabetes insipidus.

OSTEONECROSIS AND OSTEOMYELITIS

Osteonecrosis of the jaw has a number of etiologies, with medication-induced osteonecrosis of the jaws being a recently recognized and fairly common cause of devitalization of bone (Table 16-2). Osteonecrosis may, but not invariably, result in osteomyelitis.

Unlike in other bones, infection and inflammation of the jaw bones (osteitis) is a common occurrence, because teeth frequently become infected, either from caries or periodontal disease, with spread of such infection into the bone. Periapical lesions, such as periapical granuloma and apical radicular cysts when large, result in intramedullary inflammation, usually without sequestrum formation. Even large periapical abscesses heal after curettage, often without the necessity for prolonged antibiotic coverage.

Acute (painful) and chronic (usually painless) suppurative osteomyelitis of the jaws are usually the

TABLE 16-2 Etiologies for Osteonecrosis of the Jaws

Etiology	Clinical Findings	Management and Prognosis
Medication-induced: bisphosphonates and denosumab (antiosteoclastic), bevacizumab (antivascular endothelial growth factor); occurs in 1–3% of cancer patients on bisphosphonates and 1 in 2000–5000 patients on bisphosphonates for nononcologic indications.	Staging (for bisphosphonates group): 0sa or 0ss: no bone exposure, may have sinus tracts, periodontal pocketing, and/or radiographic findings; may or may not be painful Stage 1: bone exposure, no symptoms Stage 2: bone exposure, symptomatic Stage 3: extensive necrosis and/or pathologic fracture Maxilla:mandible = 1:2; often at sites of extraction, odontogenic infection, or tori	Stages 0sa and 1: chlorhexidine rinse and follow-up; nonsurgical sequestrectomy (dislodgement of bone) Stages 0ss, 2 and 3: chlorhexidine rinse, antibiotic therapy (amoxicillin, clindamycin, or metronidazole), nonsurgical or surgical sequestrectomy/excision; pain control Prognosis: Metachronous or recurrent lesions often noted
Radiation injury (damage to osteoclast precursors and sclerosis of vessels; hypovascularity); up to 5% frequency after irradiation with > 6000 cGys.	Exposed bone Maxilla:mandible = 1:9 (mandible has less collateral circulation compared with maxilla)	Surgical excision, antibiotics, chlorhexidine rinse, hyperbaric oxygen, pain control Prognosis: often difficult to control with recurrence common
Mechanical trauma		
Intubation-associated or spontaneous benign sequestration of lingual plate	Both on mylohyoid ridge	Nonsurgical sequestrectomy or allow bone to exfoliate; chlorhexidine rinse; topical analgesia Prognosis: does not recur
Chemical trauma		
Cocaine Caustic dental materials (e.g., root canal)	Cocaine necrosis often seen on palate Site where dental materials placed	Cocaine necrosis: plastic surgery Dental materials: topical steroid therapy and gentle salt water rinses Prognosis: recurrence if cocaine habit maintained
Infection		
Nonspecific/odontogenic	Nonspecific: site of odontogenic infection	Nonspecific: antibiotics, curettage, débridement, surgery, pain control
Varicella zoster	Varicella: exposed bone, unilateral, with preceding gingival/palatal ulceration	Varicella: may need to excise if does not exfoliate; antibiotics, chlorhexidine rinse, pain control Prognosis: no recurrence
Noma, necrotizing ulcerative stomatitis/NUS	Noma/NUS: around teeth and soft tissues; immunocompromised or HIV-related	Noma/NUS: improve nutrition and boost immune system, antibiotics, plastic surgery to correct soft tissue defects Prognosis: may recur if underlying medical issues not adequately addressed
Sclerotic bone disease such as mature cemento-osseous dysplasia (especially multifocal type), Paget disease, and osteopetrosis (hypovascular bone) in presence of odontogenic infection	Where bone disease and odontogenic infection coincide with/without history of extraction and oral surgery	Antibiotics, curettage, débridement, surgery, pain control Prognosis: may recur

result of odontogenic infections and are associated with sequestrum formation. Diffuse sclerosing osteomyelitis with an obvious source of infection and primary chronic osteomyelitis (seen as part of SAPHO [synovitis, acne, pustulosis, hyperostosis, osteomyelitis] syndrome) are either asymptomatic or cause a dull ache in the mandible and are not usually associated with an obvious infection.

Clinical Findings

- Please see Table 16-2.
- *Osteonecrosis:* presence of bony sequestrum, usually exposed, with or without pain (Fig. 16-48, *A* and *B*); radiographs reveal mottled radiolucency/radiopacity and often sequestrum; in the case of bisphosphonate-related osteonecrosis, chronic sinus tracts and nonhealing extraction sockets are common manifestations, and radiographs reveal thickened lamina dura and osteosclerosis (see Fig. 16-48, *C-F*).
- Benign sequestration of lingual plate consists of small, 1- to 4-mm sequestra only (see Fig. 16-48, *G*).
- *Osteomyelitis:* radiologic findings are similar to osteonecrosis but less often with exposed bone, although sinus tracts and pain are almost always present; usually occurs after extractions, and is almost always associated with a history of dental infection or, less commonly, a poorly healed fracture.

Etiopathogenesis and Histopathologic Features

Etiologies of osteonecrosis include suppression of bone turnover, vascular compromise, and trauma (see Table 16-2).

- *Bisphosphonate-related osteonecrosis and osteoradionecrosis:* nonviable bony sequestra with empty lacunae and

ragged borders, usually with extensive bacterial colonization especially with *Actinomycetes* species as a biofilm (Fig. 16-49); a diagnosis of actinomycosis (actinomycotic oseomyelitis) should be made only if sulfur granules are present, surrounded by suppuration; *Eikenella corrodens* is often present; osteoclasts are often noted in spite of antiosteoclastic activity of bisphosphonates; osteomyelitis may develop with acute and chronic inflammation and granulation tissue (Fig. 16-50).

- *Acute suppurative osteomyelitis:* nonviable bony sequestra and granulation tissue with acute and chronic inflammation.
- *Chronic osteomyelitis:* anastomosing trabeculae of viable bone that may be sclerotic with many resting and reversal lines, stromal fibrosis, and chronic inflammation; a preexisting sclerotic cemental mass may be present.

Differential Diagnosis

- A search should be made for primary bone malignancy (such as myeloma) or metastatic disease for those with bisphosphonate-related osteonecrosis; recurrent squamous cell carcinoma is a consideration for those with radiation-induced osteonecrosis.

Management and Prognosis

- Osteonecrosis: see Table 16-2; nonviable bone is often readily removed by nonsurgical sequestrectomy or dislodgement (Fig. 16-51); this yields a specimen similar to that in Figure 16-49 with little soft tissue.
- Osteomyelitis: sequestrectomy, long-term antibiotics, and possibly hyperbaric oxygen are recommended treatments.

MYOSPHERULOSIS (SPHERULOCYTOSIS, SPHERULOCYSTIC DISEASE OF SKIN)

Clinical Findings

- Radiolucency is visible at the site of a previous tooth extraction, and there is a history of the site being packed or treated for dry socket; lesion may be present for years; the tissue specimen appears tarry, oily, and black.
- Lesion is common in sinuses that have been packed and after chronic intralesional injections of the skin.

Etiopathogenesis and Histopathologic Features

Myospherulous is caused by petrolatum—or lanolin-based packing products (usually used in conjunction with antibiotics)—that undergoes an emulsification process with red blood cells.

- Altered erythrocytes appear as yellowish-brown spherical or crescent-shaped bodies within clear cystlike spaces (leached out lipid material); there is surrounding fibrosis and foreign body reaction (Fig. 16-52, *A*); some have "parent bodies" within which are endobodies (see Fig. 16-52, *B*).

Differential Diagnosis

- Fungal organisms stain with methenamine silver or PAS.

Management and Prognosis

- Curettage is curative.

HEMATOPOIETIC BONE MARROW DEFECT (OSTEOPOROTIC BONE MARROW DEFECT)

Clinical Findings

- Radiolucency in the posterior mandible, usually 0.5 to 1.0 cm, asymptomatic, often in the area of previously extracted mandibular third molar, discovered on routine radiography (Fig. 16-53).

Etiopathogenesis and Histopathologic Features

Hematopoietic marrow may represent reactive hyperplasia because of increased demand, aberrant bone regeneration, or residual fetal marrow.

- Normal hematopoietic marrow is present with all three lineages—megakaryocytes, erythrocyte precursors, and myelocytes—in various stages of maturation; fatty marrow may be present (Fig. 16-54).

Management and Prognosis

- No treatment is required.

Nonodontogenic Cysts and Cystlike Lesions

Some lesions are true cysts derived from remnants of embryogenesis, whereas others are pseudocysts (Fig. 16-55).

NASOPALATINE DUCT (INCISIVE CANAL) CYST

Clinical Findings

- Cysts may be round, ovoid, or heart shaped (because of the superimposed nasal spine seen in intraoral radiographs); symmetric radiolucency appears between the maxillary central incisors causing root divergence; adults in fourth and fifth decades are susceptible, and adjacent; teeth are vital (Fig. 16-56).

Etiopathogenesis and Histologic Features

The epithelium derives from remnants of the nasopalatine duct that runs from the floor of the posterior nasal cavity anteriorly to the midline of the palate.

- Lining is nonkeratinized stratified squamous, low cuboidal, or pseudostratified, columnar and ciliated with scattered mucous cells; the basement membrane may be densely hyalinized; the nasopalatine neurovascular bundle is usually present (Fig. 16-57).

Differential Diagnosis

- Cyst removed in the same area but not within bone is the cyst of the incisive papilla, and this has similar histology (see Chapter 2).

Management and Prognosis

- Excision is curative.

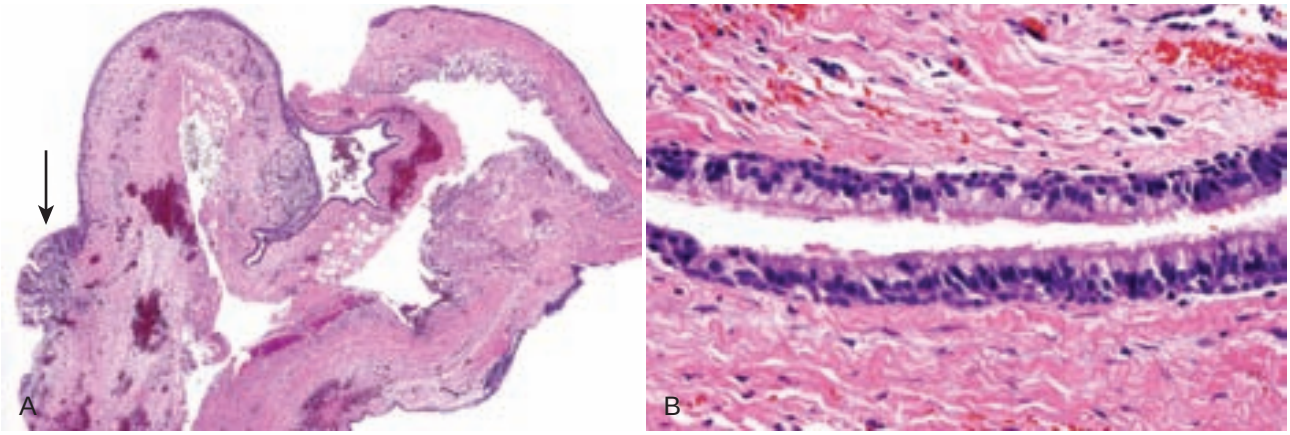

FIGURE 16-57. Nasopalatine duct cyst. **A,** Cyst lined by uniformly thin epithelium; epithelium becomes proliferative if inflamed (*arrow*). **B,** Lining composed of ciliated pseudostratified columnar epithelium.

SURGICAL CILIATED CYST (POSTOPERATIVE MAXILLARY CYST)

Clinical Findings

- Cyst occurs in third to sixth decade; it manifests as a unilocular radiolucency of the posterior maxilla with a history of surgery involving the sinuses (Fig. 16-58); cyst is rarely reported in the mandible; up to 20% of patients in the Japanese population develop this cyst after surgery.

Etiopathogenesis and Histopathologic Features

The cyst epithelium is derived from surgical (traumatic) implantation of sinus respiratory epithelium during surgical procedures such as a Le Fort I or Caldwell-Luc procedure. Mandibular cysts occur if mandibular surgery is performed immediately after sinomaxillary surgery using the same instruments.

- Lining consists of ciliated pseudostratified columnar and cuboidal epithelium two to five cells thick with mucous cells in most cases; transitional and squamous epithelium may be present; variable (usually mild) inflammation occurs in the wall (Figs. 16-59 and 16-60).

Differential Diagnosis

- Apical radicular cyst (see Chapter 14) in the posterior maxilla may be lined by respiratory epithelium, but it is always associated with a nonvital tooth without a history of sinus surgery.

Management and Prognosis

- Excision is curative.

MEDIAN PALATAL (PALATINE) CYST

This is an extremely rare cyst; its existence has been questioned. Bona fide examples are too posteriorly located to represent odontogenic or nasopalatine duct cysts as some suggest.

Clinical Findings

- Cyst occurs in the fourth decade, with a 4:1 male predilection; swelling occurs in the midline of the palate posterior to, and not in communication with, the contents of the nasopalatine foramen (Fig. 16-61).

Etiopathogenesis and Histopathologic Features

The lining arises from entrapped epithelium during fusion of the lateral palatal shelves.

- The cyst is lined by ciliated, pseudostratified columnar or uniformly thin nonkeratinized, stratified squamous epithelium.

Differential Diagnosis

- Posterior extension of the nasopalatine duct cyst should be considered, but this communicates with the nasopalatine foramen.
- If it is parakeratinized and fulfills the histologic criteria for a keratocystic odontogenic tumor (odontogenic keratocyst), then it is likely a posterior extension of a primordial cyst of a mesiodens.

Management and Prognosis

- Enucleation is curative.

ANEURYSMAL BONE CYST

Aneurysmal bone cyst, simple bone cyst, and Stafne bone cavity are pseudocysts that are not lined by epithelium.

Clinical Findings

- Ninety percent of those affected are younger than age 30; there is swelling of the face (sometimes rapid); the lesion manifests as an uniloculated or more often multiloculated, expansile radiolucency with a sclerotic rim of reactive bone and delicate intralesional trabeculae; the mandible is usually affected (75% to 90%) (Fig. 16-62); fluid level from hemorrhage is noted on imaging studies and aspiration yields blood.
- The lesion may occur secondary to another condition, such as fibrous dysplasia, ossifying fibroma, or other intraosseous neoplasms.

Etiopathogenesis and Histopathologic Features

The etiology is unknown, although trauma and local alteration of blood supply have been postulated as possible triggers. Extracranial lesions show translocations associated with chromosomes 16q22 and 17p13 in one third of cases. Primary aneurysmal bone cyst may have a different etiology from secondary lesions.

- Variably-sized, blood-filled spaces are surrounded by fibrous and granulation tissue and macrophages focally rimmed by multinucleated giant cells; fresh hemorrhage and siderophages are noted (Fig. 16-63); reactive or residual bone is a frequent finding and should not be overdiagnosed as a synchronous fibro-osseous lesion; 10% of lesions perforate the cortex.

Differential Diagnosis

- Central giant cell granuloma and giant cell lesions of Noonan and Noonan-like giant cell lesion syndromes do not contain large blood-filled spaces, although it may be difficult to see these in a curetted specimen.
- Cherubism has specific clinical, radiographic, and genetic findings.

Management and Prognosis

- Curettage, excision, resection, and percutaneous sclerotherapy are treatment modalities; recurrence in 10% to 15% of cases is likely from incomplete removal; rarely, cases regress spontaneously.

SIMPLE BONE CYST (TRAUMATIC BONE CYST, IDIOPATHIC BONE CAVITY)

Clinical Findings

- Seventy-five percent of cysts are seen in the first two decades with a slight male predilection; 75% are in the mandibular molar-premolar area, and it is rare in maxilla; unilocular radiolucency measuring up to several centimeters sometimes scallops between the roots of teeth (Fig. 16-64); surgeon will report presence of serosanguineous fluid or empty cavity with only small wisps of tissue clinging to the walls; patients rarely recall an associated history of trauma.
- This condition is associated with long-standing cementoosseous dysplasia.

Etiopathogenesis and Histopathologic Features

The most widely accepted theory is that trauma causes a hematoma that leads to venous stasis and bone ischemia, but for unknown reasons, bone remodeling does not occur.

- Small fragments of fibrovascular tissue, hemorrhage, and bone fragments or calcified debris disproportionate to the size of the clinical lesion are present (Fig. 16-65).

Management and Prognosis

- Curettage to induce clot and granulation tissue formation with subsequent reorganization to form bone is recommended treatment; 20% to 25% of cases recur, usually within the first 3 years of treatment.

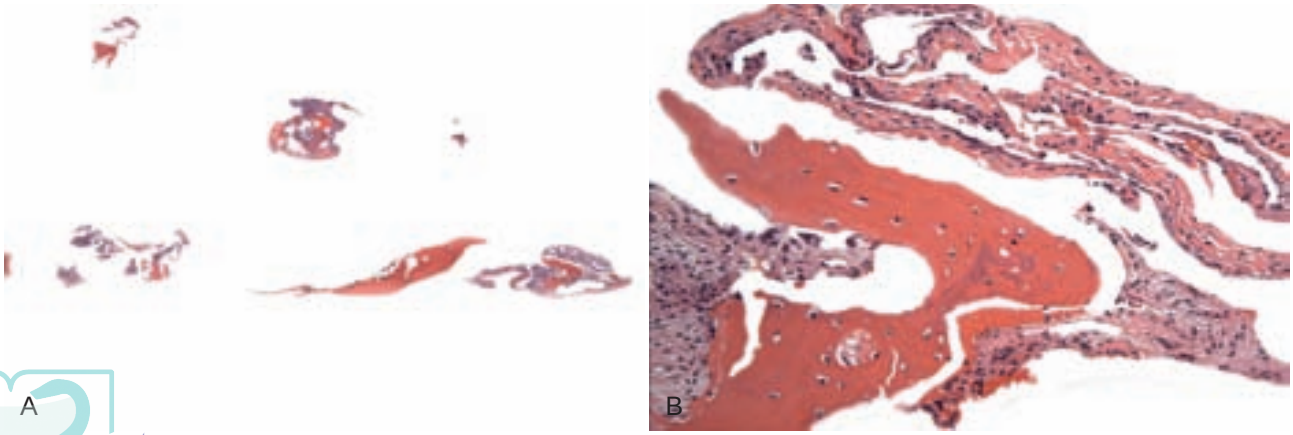

FIGURE 16-65. Simple bone cyst. **A,** Small fragments of fibrovascular tissue and bone curetted from the walls of an empty cavity at surgery. **B,** Fibrovascular tissue and viable bone.

STAFNE BONE CAVITY (LINGUAL SALIVARY GLAND DEPRESSION)

Clinical Findings

- Occurs in fifth to seventh decade; 6:1 male predilection; well-demarcated radiolucency 0.5 to 2 cm in diameter; most common location in the lingual posterior mandible beneath inferior alveolar canal (85% of cases), anterior mandible (12%), and lingual ramus (2%); asymptomatic and discovered on routine radiography (Fig. 16-66)

Etiopathogenesis and Histopathologic Features

Entrapped lobe of the sublingual or submandibular (rarely parotid) salivary gland exerts pressure on the cortex of the mandible, leading to pressure resorption.

- Tissue consists of lobules of normal seromucinous glands.

Management and Prognosis

- Lesion is well visualized and diagnostic in three-dimensional imaging studies; biopsy is not indicated.

APPENDIX A

Pharmacologic Therapy for Common Mucosal Conditions

Medication	How to Prescribe
Topical Immunosuppressive Agents	
Triamcinolone 0.1% dental paste* (not appropriate for diffuse lesions)	Apply to affected site 3–4 times a day; methylcellulose is an effective covering agent, although steroid is only medium strength
Fluocinolone 0.05% gel Clobetasol 0.05% gel Betamethasone 0.05% gel Tacrolimus 0.1% ointment	Dry area, apply to affected site 3–4 times a day; no food or drink for 20 min after OR Place gel in stent and wear for 15–30 min, 2–3 times a day
Dexamethasone elixir 0.5 mg/5mL Prednisolone syrup (15 mg/5mL) Tacrolimus solution (5 mg/mL) Cyclosporine (100 mg/mL)	Dispense 300 mL; swish 5 mL (dexamethasone, tacrolimus or cyclosporine), or 5–15 mL (prednisolone) for 3 min (timed) and spit out, 3–4 times a day; no food or drink for 20 min after
Topical tetracycline (0.25%) or minocycline (0.2%) aqueous solution	Dispense 300 mL; swish 5–15 mL for 3 min (timed) and spit out, 3–4 times a day; no food or drink for 20 min after
Nasal sprays used orally (such as fluticasone, betamethasone, and budesonide)	1–2 puffs two to three times daily
Intralesional steroid injection with triamcinolone	5–10 mg triamcinolone per cm^2 of ulceration
Systemic Immunosuppressive Therapy†	
Prednisone	1.0 mg/kg to begin for 7–10 days with a rapid taper over 2–3 weeks
Pentoxifylline (especially for aphthous ulcers)	400–800 mg three times daily
Hydroxychloroquine (especially for lichen planus)	200–400 mg daily; macular pigmentary change may lead to visual impairment
Dapsone (especially for mucous membrane pemphigoid)	25 mg to begin, increasing to 75–100 mg daily; anemia (even more serious hemolytic anemia) is significant side effect
Mycophenolate mofetil (especially for pemphigus)	500–1500 mg twice daily; myelosuppression is a side effect
Colchicine (especially for aphthous ulcers)	0.6 mg once or twice daily; myelosuppression is side effect
Azathioprine	1–2 mg/kg daily; myelosuppression and liver toxicity are significant side effects
Thalidomide (especially for aphthous ulcers)	50–100 mg 2–3 times a day to begin; begin taper to maintenance dose (which may be weekly) or discontinue completely; drowsiness and paresthesia are significant side effects
Topical Pain Medications	
Viscous lidocaine 2%	Swish and spit out 5–15 mL, 3–4 times a day for pain
Benzydamine hydrochloride 0.15%	
Dyclonine hydrochloride 1%	

*Methylcellulose adhesive base can be mixed with the other stronger topical steroids.
†Topical therapy should be started concomitantly with systemic therapy.

This page intentionally left blank

APPENDIX B

ANTIFUNGAL THERAPY

Medication	How to Prescribe
Nystatin 100,000 units/mL* Nystatin pastilles 200,000 units/pastille	Dispense 300 mL; swish and spit out (or swallow) 5 mL 3–4 times a day for 7–10 days Dissolve 1–2 pastilles in mouth 3–4 times a day for 7–10 days
Amphotericin B suspension 100 mg/mL Amphotericin 10 mg lozenges	Dispense 300 mL; swish and spit out 5 mL 3–4 times a day for 7–10 days Dissolve 1–2 tablets in mouth 3–4 times a day for 7–10 days
Clotrimazole 10 mg troches*	Suck on one troche 3–5 times a day for 7–10 days (troches do not dissolve if there is prominent hyposalivation)
Ketoconazole 200–400 mg daily Miconazole 50 mg daily	Take 1 or 2 tablets twice a day for 7–10 days Dissolve in mouth once a day for 7–10 days
Fluconazole 100–200 mg daily Itraconazole 100–200 mg daily Voriconazole 200 mg bid Posaconazole 100 mg daily	Fluconazole: use as directed for 3–4 days (depending on the severity of the infection); long-term therapy may lead to resistance to fluconazole. Culture and sensitivity should be performed and itraconazole, voriconazole, and posaconazole are alternatives; may be taken 1–2 times weekly for prophylaxis if on long-term immunosuppressive therapy.
Mycostatin/triamcinolone cream Miconazole oral gel Miconazole cream with/without hydrocortisone Iodoquinol/hydrocortisone 1% cream	Apply to corners of mouth tid or qid for angular cheilitis Paint onto denture base tid and wear denture; add erythromycin gel if there is residual lesion because *Staphylococcus aureus* may be involved.
Denture soaks: Nystatin 100,000 U/mL Chlorhexidine digluconate 0.12–2% 3% sodium hypochlorite diluted in water (1:10) 2% sodium benzoate	Soak denture in solution overnight. Dentures should never be worn overnight.

*Contains cariogenic sugars and may lead to caries if used long term.
